# MIMD Systems

Asynchronous (the processes work independently).

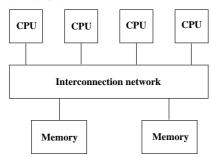

- Shared-memory systems. The programmer sees one big memory. The physical memory can be distributed.
- Distributed-memory systems.

  Each processor has its own memory. The programmer has to partition the data.

The terminology is slightly confusing. A shared memory system usually has distributed memory (distributed shared memory). Hardware & OS handle the administration of memory.

Shared memory

Bus-based architecture

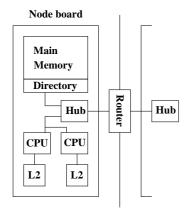

- Limited bandwidth (the amount of data that can be sent through a given communications circuit per second).
- Do not scale to a large number of processors. 30-40 CPUs common.

168

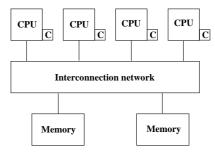

- Any processor can access any memory module. Any other processor can simultaneously access any other memory module.
- Expensive.
- Common with a memory hierarchy. Several crossbars may be connected by a cheaper network. NonUniform Memory Access (NUMA).

Example of a NUMA architecture: SGI Origin 2000, R10000 CPUS connected by a fast network.

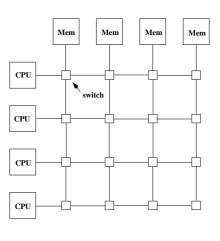

The hub manages each processor's access to memory (both local and remote) and I/O. Local memory accesses can be done independently of each other. Accessing remote memory is more complicated and takes more time.

To work well each CPU has a cache (a local memory) for temporary storage.

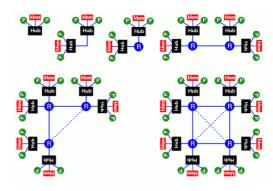

I have denoted the caches by C. Cache coherence.

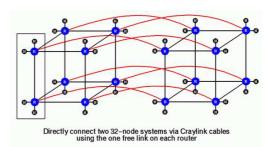

Common to use a switch to increase the bandwidth. Crossbar:

169

More than two nodes are connected via a router. A router has six ports. Hypercube configuration. When the system grows, add communication hardware for scalability.

Two important parameters of a network:

Latency is the startup time (the time it takes to send a small amount of data, e.g. one byte).

Bandwidth is the other important parameter. How many bytes can we transfer per second (once the communication has started)?

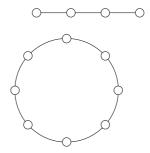

A simple model for communication:

 $time\ to\ transfer\ n\ bytes\ =\ latency + n\ /\ bandwidth$ 

## Distributed memory

In a distributed memory system, each processor has its own private memory. A simple distributed memory system can be constructed by a number of workstations and a local network.

Some examples:

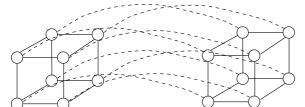

A linear array and a ring (each circle is a CPU with memory).

Hypercubes of dimensions 0, 1, 2 and 3.

173

172

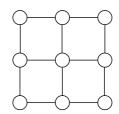

A 4-dimensional hypercube. Generally, a hypercube of dimension d+1 is constructed by connecting corresponding processors in two hypercubes of dimension d.

If d is the dimension we have  $2^d$  CPUs, and the shortest path between any two nodes is at most d steps (passing d wires). This is much better than in a linear array or a ring. We can try to partition data so that the most frequent communication takes place between neighbours.

A high degree of connectivity is good because it makes it possible for several CPUs to communicate simultaneously (less competition for bandwidth). It is more expensive though.

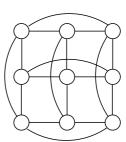

If the available connectivity (for a specific machine) is sufficient depends on the problem and the data layout.

This is a mesh:

We can have meshes of higher dimension.

If we connect the outer nodes in a mesh we get a torus:

174

#### A Note on Cluster Computing

Many modern parallel computers are built by off-the-shelf components, using personal computer hardware, Intel CPUs and Linux. Some years ago the computers were connected by an Ethernet network but faster (and more expensive) technologies are available. To run programs in parallel, explicit message passing is used (MPI, PVM).

The first systems were called Beowulf computers named after the hero in an Old English poem from around year 1000. They are also called Linux clusters and one talks about cluster computing.

In the poem, Beowulf, a hero of a tribe, from southern Sweden, called the Geats, travels to Denmark to help defeat Grendel (a monster), Grendel's mother and a dragon.

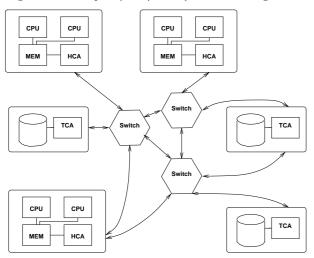

The first few lines (of about 3000) first in Old English and then in modern English:

wees on burgum
Beowulf Scyldinga,
leof leodcyning, longe þrage
folcum gefræge (fæder ellor hwearf,
aldor of earde), omæt him eft onwoc
heah Healfdene; heold þenden lifde,
gamol ond guareouw, glæde Scyldingas.

Now Beowulf bode in the burg of the Scyldings, leader beloved, and long he ruled in fame with all folk, since his father had gone away from the world, till awoke an heir, haughty Healfdene, who held through life, sage and sturdy, the Scyldings glad.

176

InfiniBand uses a switched fabric topology so several devices can share the network at the same time (as opposed to a bus topology). Data is transmitted in packets of up to 4 kB. All transmissions begin or end with a channel adapter. Each processor contains a host channel adapter (HCA) and each peripheral has a target channel adapter (TCA). It may look something like this:

Switches forward packets between two of their ports based on an established routing table and the addressing information stored on the packets. A subnet, like the one above, can be connected to another subnet by a router.

Each channel adapter may have one or more ports. A channel adapter with more than one port, may be connected to multiple switch ports. This allows for multiple paths between a source and a destination, resulting in performance and reliability benefits.

A look at the Lenngren cluster at PDC

PDC (Parallell-Dator-Centrum) is the Center for Parallel Computers, Royal Institute of Technology in Stockholm.

Lenngren (after the Swedish poet Anna Maria Lenngren, 1754-1817) is a distributed memory computer from Dell consisting of 442 nodes. Each node has two 3.4GHz EMT64-Xeon processors (EM64T stands for Extended Memory x 64-bit Technology) and 8GB of main memory. The peak performance of the system is 6Tflop/s. The nodes are connected with gigabit ethernet for login and filesystem traffic. A high performance Infiniband network from Mellanox is used for the MPI traffic.

A word on Infiniband. First a quote from http://www.infinibandta.org/

"InfiniBand is a high performance, switched fabric interconnect standard for servers. ... Founded in 1999, the InfiniBand Trade Association (IBTA) is comprised of leading enterprise IT vendors including Agilent, Dell, Hewlett-Packard, IBM, SilverStorm, Intel, Mellanox, Network Appliance, Oracle, Sun, Topspin and Voltaire. The organization completed its first specification in October 2000."

Another useful reference is http://en.wikipedia.org

InfiniBand uses a bidirectional serial bus, 2.5 Gbit/s in each direction. It also supports double and quad data rates for 5 Gbit/s or 10 Gbit/s respectively. For electrical signal reasons 8-bit

symbols are sent using 10-bits (8B/10B encoding), so the actual data rate is  $4/5 {\rm ths}$  of the raw rate.

Thus the single, double and quad data rates carry 2, 4 or 8 Gbit/s respectively.

Links can be aggregated in units of 4 or 12, called 4X or 12X. A quad-rate 12X link therefore carries 120 Gbit/s raw, or 96 Gbit/s of user data.  $_{177}$ 

#### A simple example

Consider the following algorithm (the power method). A is a square matrix of order n (n rows and columns) and  $x^{(k)}$ ,  $k = 1, 2, 3, \ldots$  a sequence of column vectors, each with n elements.

```
\begin{array}{l} x^{(1)} = random \ vector \\ \text{for k} = 1,\,2,\,3,\,\ldots \\ x^{(k+1)} = Ax^{(k)} \\ \text{end} \end{array}
```

If A has a dominant eigenvalue  $\lambda$  ( $|\lambda|$  is strictly greater than all the other eigenvalues) with eigenvector x, then  $x^{(k)}$  will be a good approximation of an eigenvector for sufficiently large k (provided  $x^{(1)}$  has a nonzero component of x).

An Example:

```
>> A=[-10 3 6;0 5 2;0 0 1] % it is not necessary
                           % that A is triangular
A =
   -10
           3
                 6
          5
                2
     0
           0
     0
>> x = randn(3, 1);
  for k = 1:8, x(:, k+1) = A*x(:, k); end
>> x(:,1:4)
  -6.8078e-01
                5.0786e+00
                            -5.0010e+01
                                          5.1340e+02
   4.7055e-01
                1.3058e+00
                             5.4821e+00
                                          2.6364e+01
  -5.2347e-01
               -5.2347e-01 -5.2347e-01
                                         -5.2347e-01
>> x(:,5:8)
  -5.0581e+03
                5.0970e+04
                           -5.0774e+05
                                          5.0872e+06
  1.3077e+02
               6.5281e+02
                            3.2630e+03
                                          1.6314e+04
  -5.2347e-01 -5.2347e-01
                            -5.2347e-01 -5.2347e-01
```

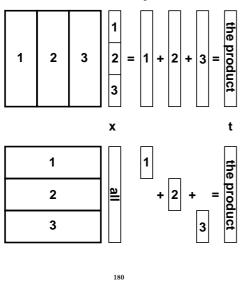

Note that  $x^{(k)}$  does not "converge" in the ordinary sense. We may have problems with over/underflow.

Revised algorithm, where we scale  $x^{(k)}$  and keep only one copy.

```
x = random\ vector x = x\ (1/\max(|x|)) Divide by the largest element for k = 1, 2, 3, ... t = Ax x = t\ (1/\max(|t|))
```

 $\lambda$  can be computed in several ways, e.g.  $x^TAx/x^Tx$  (and we already have t=Ax). In practice we need to terminate the iteration as well. Let us skip those details.

How can we make this algorithm parallel on a distributed memory MIMD-machine (given A)? One obvious way is to compute t=Ax in parallel. In order to do so we must know the topology of the network and how to partition the data.

Suppose that we have a ring with #p processors and that #p divides n. We partition A in blocks of  $\beta=n/\#p$  ( $\beta$  for block size) rows (or columns) each, so that processor 1 would store rows 1 through  $\beta$ , processor 2 rows  $1+\beta$  through  $2\beta$  etc. Let us denote these blocks of rows by  $A_1, A_2, \ldots, A_{\#p}$ . If we partition t in the same way  $t_1$  contains the first  $\beta$  elements,  $t_2$  the next  $\beta$  etc, t can be computed as:

$$\begin{bmatrix} t_1 \\ t_2 \\ \vdots \\ t_{\#p} \end{bmatrix} = Ax = \begin{bmatrix} A_1x \\ A_2x \\ \vdots \\ A_{\#p}x \end{bmatrix} \begin{array}{ll} \leftarrow \text{ on proc. 1} \\ \leftarrow \text{ on proc. 2} \\ \vdots \\ \leftarrow \text{ on proc. } \#p \\ \end{bmatrix}$$

In order to perform the next iteration processor one needs  $t_2, \ldots, t_{\# p}$ , processor two needs  $t_1, t_3, \ldots, t_{\# p}$  etc.

The processors must communicate, in other words.

Another problem is how each processor should get its part,  $A_j$ , of the matrix A. This could be solved in different ways:

- ullet one CPU gets the task to read A and distributes the parts to the other processors
- $\bullet$  perhaps each CPU can construct its  $A_j$  by computation
- perhaps each CPU can read its part from a file (or from files)

Let us assume that the  $A_j$  have been distributed and look at the matrix-vector multiply.

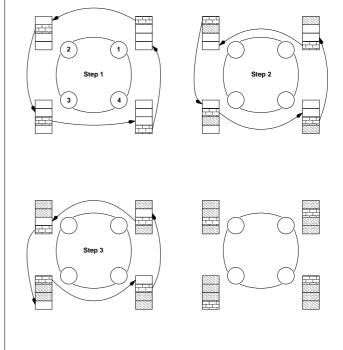

181

Processor number p would do the following (I have changed the logic slightly):

```
p = which\_processor\_am\_i() \quad (1, 2, \dots, \#p)
for k = 0, 1, 2, ... do
  if (k == 0) then
                                not so nice (but short)
   x_p = random\ vector of length \beta
  else
   t_p = A_p x
   \mu=1/\max(\mu_1,\mu_2,\ldots,\mu_{\#p})
   x_p = \mu \ t_p
  end if
 \mu_p = \max(|x_p|)
  seg = p
 for j = 1 to \#p - 1 do
   send x_{seg}, \mu_{seg} to the next processor
   receive x_{seg}, \mu_{seg} from the previous processor
  end do
end do
```

An alternative to computing seg is to send a message containing seg; "send seg, "seg,  $\mu_{seg}$ ". The program looks very much like a SIMD-program.

Here is an image showing (part of) the algorithm, when #p=4. White boxes show not yet received parts of the vector. The brick pattern shows the latest part of the vector and the boxes with diagonal lines show old pieces.

Some important terminology:

Let wct (wallclock time) be the time we have to wait for the run to finish (i.e. not the total cputime). wct is a function of #p, wct(#p) (although it may not be so realistic to change #p in a ring.

This is a simple model of this function (for one iteration):

$$wct(\#p) = rac{2n^2}{\#p}T_{flop} + (\#p-1)\left[T_{lat} + rac{n}{\#p}T_{bandw}
ight]$$

where  $T_{flop}$  is the time for one flop,  $T_{lat}$  is the latency for the communication and  $T_{bandw}$  is time it takes to transfer one double precision number.

It is often the case that (roughly):

$$wct(\#p) = seq. \ part \ of \ comp. + \frac{parallel \ part \ of \ comp.}{\#p} +$$
 $\#p \ (communication)$ 

wct has a minimum with respect to #p (it is not optimal with  $\#p = \infty$ ). The computational time decreases with #p but the communication increases.

The speedup is defined as the ratio:

$$speedup(\#p) = \frac{wct(1)}{wct(\#p)}$$

What we hope for is linear speedup, i.e. speedup(#p) = #p.

184

Instead of studying how the speedup depends on #p we can fix #p and see what happens when we change the size of the problem n. Does the speedup scale well with n? In our case:

$$egin{aligned} speedup(n) &= rac{2n^2T_{flop}}{rac{2n^2T_{flop}}{\# p} + (\# p - 1)\left[T_{lat} + rac{nT_{bandw}}{\# p}
ight]} \ &= rac{\# p}{1 + (\# p - 1)\left[rac{\# pT_{lat}}{2n^2T_{flop}} + rac{T_{bandw}}{2nT_{flop}}
ight]} \end{aligned}$$

So

$$\lim_{n\to\infty} speedup(n) = \#p$$

This is very nice! The computation is  $\mathcal{O}(n^2)$  and the communication is  $\mathcal{O}(n)$ . This is not always the case.

Exercise: partition A by columns instead.

What happens if the processors differ in speed and amount of memory? We have a load balancing problem.

Static load balancing: find a partitioning  $\beta_1, \beta_2, \ldots, \beta_{\#p}$  such that processor p stores  $\beta_p$  rows and so that wct is minimized over this partitioning. We must make sure that a block fits in the available memory on node p. This leads to the optimization problem:

$$\min_{eta_1,eta_2,...,eta_{\#p}} wct(eta_1,eta_2,\ldots,eta_{\#p}),$$

subject to the equality constraint  $\sum_{p=1}^{\# p} \beta_p = n$  and the p inequality constraints  $8n\beta_p \leq M_p$ , if  $M_p$  is the amount of memory (bytes) available on node p.

If you have a problem to solve (rather than an algorithm to study) a more interesting definition may be:

$$speedup(\#p) = \frac{time\ for\ best\ implementation\ on\ one\ processor}{wct(\#p)}$$

It is possible to have super linear speedup, speedup(#p) > #p; this is usually due to better cache locality or decreased paging.

If our algorithm contains a section that is sequential (cannot be parallelized), it will limit the speedup. This is known as Amdahl's law. Let us denote the sequential part with with s,  $0 \le s \le 1$  (part wrt time), so the part that can be parallelized is 1-s. Hence,

$$speedup(\#p) = \frac{1}{s + (1-s)/\#p} \leq \frac{1}{s}$$

regardless of the number of processors.

If you have to pay for the computer time (or if you share resources) the efficiency is interesting. The efficiency measures the fraction of time that a typical processor is usefully employed.

$$efficiency(\#p) = \frac{speedup(\#p)}{\#p}$$

We would like to have efficiency(#p) = 1.

The proportion of unused time per processor is:

$$\frac{wct(\#p) - \frac{wct(1)}{\#p}}{wct(\#p)} = 1 - \frac{wct(1)}{wct(\#p)\#p} = 1 - efficiency(\#p)$$

185

• the amount of work varies with time

Τf

- we share the processors with other users
- processors crash (#p changes)

we may have to rebalance; dynamic load balancing.

Even if the processors are identical (and with equal amount of memory) we may have to compute a more complicated partitioning. Suppose that A is upper triangular (zeros below the diagonal). (We would not use an iterative method to compute an eigenvector in this case.) The triangular matrix is easy to partition, it is worse if A is a general sparse matrix (many elements are zero).

Some matrices require a change of algorithm as well. Suppose that A is symmetric,  $A = A^T$  and that we store A in a compact way (only one triangle).

Say, 
$$A = U^T + D + U$$
 (Upper<sup>T</sup> + Diagonal + Upper).

If we store U and D by rows it is easy to compute Ux+Dx using our row-oriented algorithm. To compute  $U^Tx$  requires a column-oriented approach (if U is partitioned by rows,  $U^T$  will be partitioned by columns, and a column-oriented algorithm seems reasonable). So the program is a combination of a row and a column algorithm.

#### A few words about communication

In our program we had the loop:

```
for j=1 to \#p-1

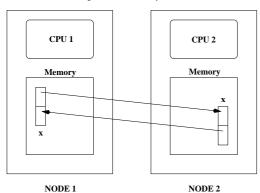

send x_{seg}, \mu_{seg} to the next processor

compute seg

receive x_{seg}, \mu_{seg} from the previous processor

end
```

Suppose #p=2 and that we can transfer data from memory (from  $x_1$  on processor one to  $x_1$  on processor two, from  $x_2$  on processor two to  $x_2$  on processor one).

There are several problems with this type of communication, e.g.:

- ullet if CPU 1 has been delayed it may be using  $x_2$  when CPU 2 is writing in it
- several CPUs may try to write to the same memory location (in a more general setting)
- $\bullet$  CPU 1 may try to use data before CPU 2 has written it

So, a few things we would like to able to do:

- wait for a message until we are ready to take care of it
- do other work while waiting (to check now and then)
- find out which processor has sent the message
- have identities of messages (one CPU could send several; how do we distinguish between them)
- see how large the message is before unpacking it
- send to a group of CPUs (broadcast)

An obvious way to solve the first problem is to use synchronisation. Suppose CPU 1 is delayed. CPU 2 will send a "ready to send"-message to CPU 1 but it will not start sending data until CPU 1 has sent a "ready to receive"-message.

This can cause problems. Suppose we have a program where both CPUs make a send and then a receive. If the two CPUs make sends to each other the CPUs will "hang". Each CPU is waiting for the other CPU to give a "ready to receive"-message. We have what is known as a deadlock.

One way to avoid this situation is to use a buffer. When CPU 1 calls the send routine the system copies the array to a temporary location, a buffer. CPU 1 can continue executing and CPU 2 can read from the buffer (using the receive call) when it is ready. The drawback is that we need extra memory and an extra copy operation.

Suppose now that CPU 1 lies ahead and calls receive before CPU 2 has sent. We could then use a blocking receive that waits until the messages is available (this could involve synchronised or buffered communication). An alternative is to use a nonblocking receive. So the receive asks: is there a message? If not, the CPU could continue working and ask again later.

189

#### Process control under unix

Processes are created using the fork-system call. System call: the mechanism used by an application program to request service from the operating system (from the unix-kernel). man -s2 intro, man -s2 syscalls. printf (for example) is not a system call but a library function. man -s3 intro for details.

```
#include <sys/wait.h> /* for wait
#include <sys/types.h> * for wait and fork
#include <unistd.h>
                      /* for fork and getppid */
#include <stdio.h>
int main()
{
 int
                var, exit_stat;
 pid t
                pid;
 var = 10:
 printf("Before fork\n");
 printf("fork error\n");
   return 1;
 } else if (pid == 0) {
                           /* I am a child */
   var++;
   printf("child\n");
   sleep(60);
                           /* do some work */
 } else {
                           /* I am a parent */
   printf("parent\n");
                           /* wait for (one)
   wait(&exit stat);
                           /* child to exit; not */
                           /* necessary to wait */
 printf("ppid = %6ld, pid = %6ld, var = %d\n",
         getppid(), pid, var); # get parent proc id */
 return 0;
}
```

```
% a.out
Before fork
child
parent
ppid = 6843, pid = 0, var = 11 child
ppid = 27174, pid = 6844, var = 10 parent
```

fork creates the child process (from the parent process) by making a copy of the parent (so the child gets copies of the heap and stack for example). The child and parent continue executing with the instruction that follows the call to fork. So fork is called from the parent and returns both to the parent and the child.

Every process is identified by a number, the process id. or pid. We can list the pids (and some other properties) of all the processes running in the computer (this list has been shortened). The ps-commando takes a huge number of options.

```
% ps -fel | grep thomas
UID
           PID
                  PPID
                         CMD
          5442
                 27174
thomas
                         xterm
thomas
          5446
                  5442
                          -csh
thomas
          6843
                 27174
                          a.out <-- parent
thomas
          6844
                  6843
                         a.out <-- child
thomas
          6851
                  5446
                         ps -fel
thomas
          6852
                  5446
                          grep thomas
                 27171
thomas
         27174
                          -tcsh
                          sshd: thomas@pts/62
thomas
         27171
                 27152
                  3203
                         sshd: thomas [priv]
         27152
root
                          /usr/sbin/sshd
root
          3203
                     1
                         init [5]
                     0
root
             1
```

A process that hangs (not uncommon in parallel programming) can be terminated using the kill-command which sends a signal to a process. There are different signals and they can be used for communication between processes. Signal number 9, sigkill, cannot be caught.

```
% kill -1
HUP INT QUIT ILL TRAP ABRT BUS FPE KILL USR1 SEGV USR2
% ps U thomas
 PID TTY
               STAT
                      TIME COMMAND
8604 pts/62
                      0:00 a.out <-- kill this one
              S+
% kill -9 8604 (or kill -KILL 8604)
A process can choose to catch the signal using a a signal handler
routine. It can also ignore (some) signals:
#include <signal.h>
#include <stdio.h>
int main()
  /* SIGINT is defined /usr/include/bits/signum.h*/
 if ( sigignore(SIGINT) == -1 )
    printf("*** Error when calling sigignore.\n");
               /* loop forever */
 while(1)
 return 0:
}
% gcc signal.c
% a.out
^C^C^C^C^C^C^C^C^C^\Quit
% /bin/stty -a
intr = ^C; quit = ^\; erase = ^H; etc....
```

To start a child process that differs from the parent we use the exec system call (there are several forms). exec replaces the child (the process which it is called from) with a new program.

```
#include <sys/wait.h>
#include <sys/types.h>
#include <unistd.h>
#include <stdio.h>
int main()
{
 int
                  exit stat;
                  pid;
 pid t
  if ((pid = fork()) < 0) {</pre>
   printf("fork error\n");
   return 1:
  } else if (pid == 0) \{ /* I am a child */
    /* replace this process by another */
    /* execlp( file, name_shown_by_ps,
               argl, ..., argn, NULL)
    /* (char *) 0 is a null pointer. (char*)
       is a type cast. See the C FAQ for details.*/
    /* new is a compiled C-program*/
    if(execlp("new", "new_name", (char*) 0) < 0) {</pre>
           printf("*** execlp error\n");
            return 1:
    }
  } else
                          /* I am a parent. Wait */
    wait(&exit_stat);
                          /* or do something else */
  return 0;
Very common usage in command&.
```

193

#### Interprocess communication

Most parallel computing tasks require communication between processes. This can be accomplished in several different ways on a unix system. The pipe, |, is a standard example:

```
% ps aux | grep a.out
```

The ps and grep processes are running in parallel and are communicating using a pipe. Data flows in one direction and the processes must have a common ancestor. The pipe handles synchronisation of data (grep must wait for data from ps and ps may not deliver data faster than grep can handle, for example).

The communication is usually local to one system, but using rsh (remote shell) or ssh (secure shell) it may be possible to communicate between different computers:

```
% ps aux | ssh other_computer "grep a.out > /tmp/junk"
/tmp/junk is created on other_computer (There are other
remote commands such as rcp/scp remote copy).
```

FIFOs (or named pipes) can be used to communicate between two unrelated processes. A general way to communicate between computers over a network is to use so called sockets.

When a (parallel) computer has shared memory it is possible to communicate via the memory. Two (or more processes) can share a portion of the memory. Here comes a master (parent) program.

```
#include <sys/types.h>
#include <unistd.h>
#include <stdio.h>
#include <sys/ipc.h>
#include <sys/shm.h>
int main()
                  exit_stat, shmid, info, k;
 pid_t
                 pid:
 struct shmid_ds buf;
                *shmaddr:
  double
                 s_shmid[10];
  char
   * Create new shared memory segment and then
  * attach it to the address space of the process.
  shmid=shmget(IPC_PRIVATE, (size_t) 512, SHM_R|SHM_W);
  shmaddr = shmat(shmid, (void*) 0, 0);
  /* Store some values */
 for (k = 0; k < 512 / 8; k++)
   *(shmaddr + k) = k;
  /* Create new proces */
 if ((pid = fork()) < 0) {</pre>
   printf("fork error\n");
   return 1:
  } else if (pid == 0) {
                               /* I am a child */
```

194

```
/* convert int to string */
    sprintf(s_shmid, "%d", shmid);
    if (execlp("./child", "child_name", s_shmid,
              (char *) 0) < 0) {
      printf("*** In main: execlp error.\n");
     return 1;
  } else {
    wait(&exit_stat);
    /* Remove the segment. */
    info = shmctl(shmid, IPC_RMID, &buf);
  return 0;
Here comes a slave (child) program.
#include <stdio.h>
#include <stdlib.h>
#include <sys/ipc.h>
#include <sys/shm.h>
int main(int argc, char *argv[])
                 k. shmid:
{ int
  double
                 *shmaddr;
 printf("In child\n"); printf("argc = %d\n", argc);
 printf("argv[0] = %s\nargv[1] = %s\n",argv[0],argv[1]
 shmid = atoi(argv[1]);
                                # convert to int */
 printf("shmid = %d\n", shmid);
 shmaddr = shmat(shmid, (void*) 0, SHM_RDONLY);
 for (k = 0; k < 5; k++) /* "Fetch" and print values*/
   printf("*(shmaddr+%d) = %f\n", k,*(shmaddr + k));
  return 0;
}
                         196
```

```
% gcc -o master master.c
% gcc -o child child.c
% master
In child
argc = 2
argv[0] = child_name
argv[1] = 22183946
shmid = 22183946
*(shmaddr+0) = 0.000000
*(shmaddr+1) = 1.000000
*(shmaddr+2) = 2.000000
*(shmaddr+3) = 3.000000
*(shmaddr+4) = 4.000000
```

In general some kind of synchronisation must be used when accessing the memory. There are such tools (e.g. semaphores) but since we will look at a similar construction in the next section we drop the subject for now.

Using the command ipcs we can get a list of segments. It may look like:

```
% ipcs
----- Shared Memory Segments ------
key shmid owner perms bytes status
0x000000000 22249482 thomas 600 512 0
... more stuff
In case of problems we can remove segments, e.g.
ipcrm -m 22249482
```

197

# POSIX Threads (pthreads)

(POSIX: Portable Operating System Interface, A set of IEEE standards designed to provide application portability between Unix variants. IEEE: Institute of Electrical and Electronics Engineers, Inc. The world's largest technical professional society, based in the USA.)

Unix process creation (and context switching) is rather slow and different processes do not share much (if any) information (i.e. they may take up a lot of space).

A thread is like a "small" process. It originates from a process and is a part of that process. All the threads share global variables, files, code, PID etc. but they have their individual stacks and program counters.

When the process has started, one thread, the master thread, is running. Using routines from the pthreads library we can start more threads.

If we we have a shared memory parallel computer each thread may run on its own processor, but threads are a convenient programming tool on a uniprocessor as well.

In the example below a dot product,  $\sum_{i=1}^{n} a_i b_i$ , will be computed in parallel. Each thread will compute part of the sum. We could, however, have heterogeneous tasks (the threads do not have do do the same thing).

```
We compile by: gcc prog.c -lpthread
```

```
#include <pthread.h>
#include <stdio.h>
#include <stdlib.h>
/* global shared variables */
#define VEC LEN
#define N_THREADS 4
                 a[VEC_LEN], b[VEC_LEN], sum;
pthread_mutex_t mutexsum;
void *dotprod(void *arg) /* the slave */
{
  int
          i, start, end, i am, len;
  double mysum;
  i_am = (int) arg;
  /* assume that N_THREADS divides VEC_LEN*/
  len = VEC_LEN / N_THREADS;
  start = i_am * len;
  end = start + len;
  mysum = 0.0; /* local sum */
  for (i = start; i < end; i++)
   mysum += a[i] * b[i];
  /* update global sum with local sum*/
  pthread_mutex_lock(&mutexsum);
    sum += mysum; /* critical section */
  pthread_mutex_unlock(&mutexsum);
  /* terminate the thread, NULL is the null-pointer*/
  pthread_exit(NULL); # not really needed */
 return NULL;
                      /* to silence lint */
```

```
int main()
               thread_id[N_THREADS];
 pthread t
               i, ret;
  int
  for (i = 0; i < VEC_LEN; i++) {
   a[i] = 1.0; /* initialize */
   b[i] = a[i];
  sum = 0.0;
                  /* global sum, NOTE declared global*/
/* Initialize the mutex (mutual exclusion lock).*/
 pthread mutex init(&mutexsum, NULL);
/* Create threads to perform the dotproduct
  NUll implies default properties.
 for(i = 0; i < N_THREADS; i++)</pre>
    if( ret = pthread_create(&thread_id[i], NULL,
                            dotprod, (void *) i)){
      printf ("Error in thread create\n");
      exit(1);
/* Wait for the other threads. If the main thread
   exits all the slave threads will exit as well. */
  for(i = 0; i < N_THREADS; i++)</pre>
    if( ret = pthread_join(thread_id[i], NULL) ) {
      printf ("Error in thread join %d \n", ret);
       exit(1);
 printf ("sum = %f\n", sum);
 pthread_mutex_destroy(&mutexsum);
 return 0;
                         200
```

This is what the run looks like. Since the threads have the same PID we must give a special option to the ps-command to see them.

```
sum = 400.000000
% ps -felL | grep thomas | grep a.out (edited)
IITD
          PID PPID LWP NLWP CMD
thomas
         15483 27174 15483
                              5 a.out <-- master
thomas
        15483 27174 15484
                              5 a.out
thomas
        15483 27174 15485
                              5 a.out
thomas
        15483 27174 15486
                              5 a.out
thomas
        15483 27174 15487
```

 $\label{eq:lwp} \begin{tabular}{ll} $\tt LWP$ id. of light weight process (thread). \\ &\tt NLWP$ number of lwps in the process. \\ \end{tabular}$ 

Note that the PID is the same.

% a.out

201

#### Race conditions, deadlock etc.

When writing parallel programs it is important not to make any assumptions about the order of execution of threads or processes (e.g that a certain thread is the first to initialize a global variable). If one makes such assumptions the program may fail occasionally (if another thread would come first). When threads compete for resources (e.g. shared memory) in this way we have a race condition. It could even happen that threads deadlock (deadlock is a situation where two or more processes are unable to proceed because each is waiting for one of the others to do something).

From the web: I've noticed that under LinuxThreads (a kernel-level POSIX threads package for Linux) it's possible for thread B to be starved in a bit of code like the fragment at the end of this message (not included). I interpreted this as a bug in the mutex code, fixed it, and sent a patch to the author. He replied by saying that the behavior I observed was correct, it is perfectly OK for a thread to be starved by another thread of equal priority, and that POSIX makes no guarantees about mutex lock ordering. ... I wonder (1) if the behavior I observed is within the standard and (2) if it is, what the f%^& were the POSIX people thinking? ...

Sorry, I'm just a bit aggravated by this.

Any info appreciated,

Bill Gribble

According to one answer it is within the standard.

When I taught the course 2002, Solaris pthreads behaved this way, but this has changed in Solaris 9. Under Linux (2005) there are no problems, so I will not say more about this subject.

#### Message Passing Software

Several packages available. The two most common are PVM (Parallel Virtual Machine) and MPI (Message Passing Interface).

The basic idea in these two packages is to start several processes and let these processes communicate through explicit message passing. This is done using a subroutine library (Fortran & C). The subroutine library usually uses unix sockets (on a low level). It is possible to run the packages on a shared memory machine in which case the packages can communicate via the shared memory. This makes it possible to run the code on many different systems.

In MPI one has to work a bit more to send a message consisting of several variables. In PVM it is possible to start processes dynamically, and to run several different a.out-files. In MPI the processes must be started using a special unix-script and only one a.out is allowed (at least in MPI version 1).

PVM is available in one distribution, pvm3.4.4 (see the home page). (Al Geist, Adam Beguelin, Jack Dongarra, Weicheng Jiang, Robert Manchek, Vaidy Sunderam.) Free book available on the net (PostScript & HTML).

Some of the systems PVM runs on (this is an old list; systems have been added):

AFX8, Alliant FX/8, ALPHA, DEC Alpha/OSF-1, ALPHAMP, DEC Alpha/OSF-1 / using shared memory, APOLLO, HP 300 running Domain/OS, ATT, AT&T/NCR 3600 running SysVR4, BAL, Sequent Balance, BFLY, BBN Butterfly TC2000, BSD386, 80[345]86 running BSDI or BSD386, CM2, Thinking Machines CM-2 Sun front-end, CM5, Thinking Machines CM-5, CNVX, Convex using IEEE floating-point, CNVXN, Convex using native f.p., CRAY, Cray, CRAY2, Cray-2, CRAYSMP, Cray S-MP, CSPP, Convex Exemplar, DGAV, Data General Aviion, E88K, Encore 88000, FREEBSD, 80[345]86 running FreeBSD, HP300, HP 9000 68000 cpu, HPPA, HP 9000 PA-Risc, HPPAMP, HP 9000 PA-Risc / shared memory transport, KSR1, Kendall Square, 1860, Intel RX Hypercube, IPSC2, Intel IPSC/2, LINUX, 80[345]86 running Linux, M88K, Motorola M88100 running Real/IX, MASPAR, Maspar, MIPS, Mips, NETB-SDAMIGA, Amiga running NetBSD, NETBSDHP300, HP 300 running NetBSD,  $NETBSDI386,\ 80[345]86\ running\ NetBSD,\ NETBSDMAC68K,\ Macintosh\ running$ NetBSD, NETBSDPMAX, DEC Pmax running NetBSD, NETBSDSPARC, Sparc running NetBSD, NETBSDSUN3, SUN 3 running NetBSD, NEXT, NeXT, PGON, Intel Paragon, PMAX, DEC/Mips arch (3100, 5000, etc.), RS6K, IBM/RS6000, RS6KMP, IBM SMP / shared memory transport, RT, IBM/RT, SCO, 80[345]86 running SCO Unix, SGI, Silicon Graphics IRIS, SGI5, Silicon Graphics IRIS running OS > 5.0, SGI64, Silicon Graphics IRIS running OS  $\geq$  6.0, SGIMP, Silicon Graphics IRIS / OS 5.x / using shared memory, SGIMP64, Silicon Graphics IRIS / OS 6.x / using shared memory, SP2MPI, IBM SP-2 / using MPI, SUN3, Sun 3, SUN4, Sun 4, 4c, sparc, etc., SUN4SOL2, Sun 4 running Solaris 2.x, SUNMP, Sun 4 / using shared memory / Solaris 2.x, SX3, NEC SX-3, SYMM, Sequent Symmetry, TITN, Stardent Titan, U370, IBM 3090 running AIX, UTS2, Amdahl running UTS, UVAX, DEC/Microvax, UXPM, Fujitsu running UXP/M, VCM2, Thinking Machines CM-2 Vax front-end, X86SOL2, 80[345]86 running Solaris 2.x.

204

It is possible to add machines that are far away and of different architectures. The add command start a pvmd on each machine (pvmd pvm-daemon). The pvmds relay messages between hosts.

The PVM-versions that are supplied by the vendors are based on the public domain (pd) version.

Common to write master/slave-programs (two separate mainprograms). Here is the beginning of a master:

```
program master
#include "fpvm3.h"
  call pvmfmytid ( mytid ) ! Enroll program in pvm
 print*, 'How many slaves'
         nslaves
 read*,
 name_of_slave = 'slave' ! pvmd looks in a spec. dir.
               = '*'
                         ! any will do
```

call pvmfspawn ( name\_of\_slave, PVMDEFAULT, arch, nslaves, tids, numt )

arch

```
The beginning of the slave may look like:
  program slave
#include "fpvm3.h"
 call pvmfmytid ( mytid ) ! Enroll program in pvm
 call pvmfparent ( master ) ! Get the master's task id
     Receive data from master.
 call pvmfrecv ( master, MATCH_ANYTHING, info )
 call pvmfunpack ( INTEGER4, command, 1, 1, info )
```

There are several pd-versions of MPI. The Sun-implementation is based on mpich (Argonne National Lab.).

Here comes a simple MPI-program.

PVM can be run in several different ways. Here we add machines to the virtual machine by using the PVM-console:

```
pvm> conf
1 host, 1 data format
                   HOST
                            DTTD
                                    ARCH
                                            SPEED
  ries.math.chalmers.se
                            40000 SUN4SOL2
                                             1000
pvm> add fibonacci
1 successful
                   HOST
                            חדדם
              fibonacci
                           80000
pvm> add fourier
1 successful
                   HOST
                            DTTD
                fourier
                           c0000
pvm> add pom.unicc
1 successful
                   HOST
                            DTTD
              pom.unicc
                          100000
pvm> conf
4 hosts, 1 data format
                   HOST
                           DTID
                                    ARCH
                                            SPEED
   ries.math.chalmers.se
                           40000 SUN4SOL2
                                             1000
                           80000 SUN4SOL2
              fibonacci
                                             1000
                fourier
                          c0000 SUN4SOL2
                                             1000
              pom.unicc
                         100000
                                    SUNMP
                                             1000
pvm> help
help - Print helpful information about a command
Syntax: help [ command ]
Commands are:
 add - Add hosts to virtual machine
  alias - Define/list command aliases
  conf - List virtual machine configuration
  delete - Delete hosts from virtual machine
  etc.
pvm> halt
```

```
#include <stdio.h>
#include "mpi.h"
                    /* Important */
int main(int argc, char*argv[])
{
                 message, length, source, dest, tag;
                 n procs; /* number of processes */
 int
                 my_rank; /* 0, ..., n_procs-1 */
 MPI Status
                 status:
 MPI_Init(&argc, &argv);  # Start up MPI */
  /* Find out the number of processes and my rank*/
 MPI_Comm_size(MPI_COMM_WORLD, &n_procs);
 MPI Comm rank(MPI COMM WORLD, &my rank);
        = 1;
  tag
  length = 1;
                    /* Length of message
  if (my_rank == 0) { /* I'm the master process */
   printf("Number of processes = %d\n", n_procs);
                    /* Send to the other process */
   dest = 1;
   message = 1;
                    /* Just send one int
    /* Send message to slave */
   MPI_Send(&message, length, MPI_INT, dest,
            tag, MPI_COMM_WORLD);
   printf("After MPI_Send\n");
   source = 1:
    /* Receive message from slave. length is how much
      room we have and NOT the length of the message*/
   MPI_Recv(&message, length, MPI_INT, source, tag,
            MPI_COMM_WORLD, &status);
   printf("After MPI Recv, message = %d\n", message);
```

```
} else {
             /* I'm the slave process*/
    source = 0;
    /* Receive message from master*/
    MPI_Recv(&message, length, MPI_INT, source, tag,
             MPI_COMM_WORLD, &status);
    dest = 0; /* Send to the other process*/
    message++; /* Increase message */
    /* Send message to master */
    MPI_Send(&message, length, MPI_INT, dest,
             tag, MPI_COMM_WORLD);
 MPI_Finalize();
                   /* Shut down MPI */
 return 0;
}
To run: read the MPI-assignment. Something like:
% lamboot bhost
% mpicc simple.c
% mpirun c0-1 a.out
Number of processes = 2
After MPI_Send
After MPI Recv, message = 2
             when we are finished for the day
% lamhalt
One can print in the slave as well, but it may not work in all
MPI-implementations and the order of the output is not
```

We may not be able to start processes from inside the program (permitted in MPI 2.0 but may not be implemented).

deterministic. It may be interleaved or buffered.

208

The two most basic communication routines (there are many) are:

If the message is an array there should be no &.

Some other datatypes are MPI\_FLOAT and MPI\_DOUBLE

MPI\_COMM\_WORLD, &status);

The Fortran names are MPI\_INTEGER, MPI\_REAL and MPI\_DOUBLE\_PRECISION

Note that length is the number of elements of the specific type (not the number of bytes).

length in MPI\_Send is the number of elements we are sending (the message-array may be longer). length in MPI\_Recv is amount of storage available to store the message.

If this value is less than the length of the message we get:

```
After MPI_SendMPI_Recv: message truncated (rank 1, MPI_COMM_WORLD)
```

One of the processes started by mpirun has exited with a nonzero exit code. ...

dest is the rank of the receiving process. tag is a number of the message that the programmer can use to keep track of messages  $(0 \le \text{tag} \le \text{at least } 32767)$ .

Let us look at each call in some detail: Almost all the MPI-routines in C are integer functions returning a status value. I have ignored these values in the example program. In Fortran there are subroutines instead. The status value is returned as an extra integer parameter (the last one).

Start and stop MPI (it is possible to do non-MPI stuff before Init and after Finalize). These routines must be called:

```
MPI_Init(&argc, &argv);
...
MPI_Finalize();
```

MPI\_COMM\_WORLD is a communicator, a group of processes. The program can find out the number of processes by calling MPI\_Comm\_size (note that & is necessary since we require a return value).

```
MPI_Comm_size(MPI_COMM_WORLD, &n_procs);
```

Each process is numbered from 0 to n\_procs-1. To find the number (rank) we can use MPI\_Comm\_rank

```
MPI_Comm_rank(MPI_COMM_WORLD, &my_rank);
```

We need the rank when sending messages and to decide how the work should be shared:

```
if ( my_rank == 0 ) {
   I'm the master
} elseif ( my_rank == 1 ) {
...
```

20

The same holds for MPI\_Recv, with the difference that source is the rank of the sender.

If we will accept a message from <u>any</u> sender we can use the constant (from the header file) MPI\_ANY\_SOURCE

If we accept any tag we can use MPI\_ANY\_TAG
So, we can use tag and source to pick a specific message from a queue of messages.

status is a so called structure (a record) consisting of at least three members (MPI\_SOURCE, MPI\_TAG and MPI\_ERROR (some systems may have additional members).

We can do the following:

```
printf("status.MPI_SOURCE = %d\n", status.MPI_SOURCE)
printf("status.MPI_TAG = %d\n", status.MPI_TAG);
printf("status.MPI_ERROR = %d\n", status.MPI_ERROR);
```

To find out the actual length of the message we can do:

```
MPI_Get_count(&status, MPI_INT, &size);
printf("size = %d\n", size);
```

Here comes the simple program in Fortran.

210

```
program simple
  implicit
             none
  include
             "mpif.h"
  integer
             message, length, source, dest, tag
 integer
             my_rank, err
             n_procs
  integer
                         ! number of processes
 integer
             status(MPI_STATUS_SIZE)
 call MPI_Init(err) ! Start up MPI
! Find out the number of n\_processes and my rank
  call MPI_Comm_rank(MPI_COMM_WORLD, my_rank, err)
  call MPI_Comm_size(MPI_COMM_WORLD, n_procs, err)
        = 1
 length = 1
              ! Length of message
  if ( my_rank == 0 ) then ! I'm the master process
   print*, "Number of processes = ", n_procs
           = 1 ! Send to the other process
   message = 1 ! Just send one integer
   Send message to slave
   call MPI_Send(message, length, MPI_INTEGER, dest, &
                 tag, MPI_COMM_WORLD, err)
    print*, "After MPI_Send"
    source = 1
   Receive message from slave
   call MPI_Recv(message, length, MPI_INTEGER, source,
                 tag, MPI_COMM_WORLD, status, err)
    print*, "After MPI_Recv, message = ", message
                        212
```

```
else ! I'm the slave process
   source = 0
   Receive message from master
   call MPI_Recv(message, length, MPI_INTEGER, source,
                 tag, MPI_COMM_WORLD, status, err)
   dest
           = 0
                           ! Send to the other process
   message = message + 1 ! Increase message
   Send message to master
   call MPI_Send(message, length, MPI_INTEGER, dest, &
                 tag, MPI_COMM_WORLD, err)
  call MPI_Finalize(err) ! Shut down MPI
end program simple
Note that the Fortran-routines are subroutines (not functions)
```

and that they have an extra parameter, err.

One problem in Fortran77 is that status, in MPI Recv. is a structure. The solution is: status(MPI\_SOURCE) status(MPI\_TAG) and status(MPI\_ERROR) contain, respectively, the source, tag and error code of the received message.

To compile and run (one can add -03 etc.):

```
mpif77 simple.f90
                   I have not made any mpif90
mpirun c0-1 a.out
```

^C usually kills all the processes.

213

There are blocking and nonblocking point-to-point Send/Receiveroutines in MPI. The communication can be done in different modes (buffered, synchronised, and a few more). The Send/Receive we have used are blocking, but we do not really know if they are buffered or not (the standard leaves this open). This is a very important question. Consider the following code:

```
integer, parameter
                         :: MASTER = 0, SLAVE = 1
                         :: N MAX = 10000
integer, parameter
integer, dimension(N_MAX) :: vec = 1
call MPI Init(err)
call MPI_Comm_rank(MPI_COMM_WORLD, my_rank, err)
call MPI_Comm_size(MPI_COMM_WORLD, n_procs, err)
msg_len = N_MAX; buf_len = N_MAX
if ( my_rank == MASTER ) then
  send to = SLAVE; tag = 1
  call MPI_Send(vec, msg_len, MPI_INTEGER,
               send_to, tag, MPI_COMM_WORLD, err)
  recv_from = SLAVE; tag = 2
  call MPI_Recv(vec, buf_len, MPI_INTEGER, &
               recv_from, tag,
               MPI_COMM_WORLD, status, err)
else
  send_to = MASTER; tag = 2
  call MPI_Send(vec, msg_len, MPI_INTEGER,
               send_to, tag, MPI_COMM_WORLD, err)
  recv from = MASTER; tag = 1
```

call MPI\_Recv(vec, buf\_len, MPI\_INTEGER, &

end if

recv\_from, tag,

MPI\_COMM\_WORLD, status, err)

This code works (under LAM) when N\_MAX = 1000, but it hangs, it deadlocks, when  $N_MAX = 10000$ . One can suspect that buffering is used for short messages but not for long ones. This is usually the case in all MPI-implementations. Since the buffer size is not standardized we cannot rely on buffering though.

There are several ways to fix the problem. One is to let the master node do a Send followed by the Receive. The slave does the opposite, a Receive followed by the Send.

```
master
call MPI_Send(...)
                       call MPI_Recv(...)
call MPI_Recv(...)
                       call MPI_Send(...)
```

Another way is to use the deadlock-free MPI\_Sendrecvroutine. As it says in the LAM man-page: "This function is guaranteed not to deadlock in situations where pairs of blocking sends and receives may deadlock."

```
The code in the example can then be written:
program dead_lock
  include "mpif.h"
  integer :: rec_from, snd_to, snd_tag, rec_tag, &
            my_rank, err, n_procs, snd_len, buf_len
  integer, dimension(MPI_STATUS_SIZE) :: status
                            :: MASTER = 0, SLAVE = 1
  integer, parameter
                             :: N_MAX = 100
  integer, parameter
  integer, dimension(N_MAX) :: snd_buf, rec_buf
  call MPI Init(err)
  call MPI_Comm_rank(MPI_COMM_WORLD, my_rank, err)
 call MPI_Comm_size(MPI_COMM_WORLD, n_procs, err)
  snd_len = N_MAX;
                      buf_len = N_MAX
```

```
if ( my rank == MASTER ) then
   snd_buf = 10 ! init the array
   snd_to = SLAVE; snd_tag = 1
rec_from = SLAVE; rec_tag = 2
   call MPI_Sendrecv(snd_buf, snd_len, MPI_INTEGER, &
                 snd_to, snd_tag, rec_buf, buf_len, &
                 MPI_INTEGER, rec_from, rec_tag,
                MPI_COMM_WORLD, status, err)
   print*, 'master, rec_buf(1:5) = ', rec_buf(1:5)
  else
   snd_buf = 20 ! init the array
   snd_to = MASTER; snd_tag = 2
   rec_from = MASTER; rec_tag = 1
    call MPI_Sendrecv(snd_buf, snd_len, MPI_INTEGER, &
                 snd_to, snd_tag, rec_buf, buf_len, &
                 MPI_INTEGER, rec_from, rec_tag,
                 MPI_COMM_WORLD, status, err)
   print*, 'slave, rec_buf(1:5) = ', rec_buf(1:5)
  end if
 call MPI_Finalize(err)
end program dead_lock
% mpirun c0-1 ./a.out
master, rec_buf(1:5) = 20 20 20 20 20
slave, rec_buf(1:5) = 10 10 10 10 10
Another situation where we get a deadlock is when a send is
missing:
                                 slave
```

```
master slave ... call MPI_Recv(...)
```

A blocking receive will wait forever (until we kill the processes).

216

```
% mpirun c0-3 a.out
0: message[0..2] = 0 1 2
1: message[0..2] = 0 1 2
3: message[0..2] = 0 1 2
```

Why should we use a broadcast instead of several MPI\_Send? The answer is that it may be possible to implement the broadcast in a more efficient manner:

```
timestep 0: 0 -> 1 (-> means send to)

timestep 1: 0 -> 2, 1 -> 3

timestep 2: 0 -> 4, 1 -> 5, 2 -> 6, 3 -> 7

etc.
```

So, provided we have a network topology that supports parallel sends we can decrease the number of send-steps significantly. In lam this is used if n\_procs is greater than four. Otherwise a linear algorithm is used.

# Sending messages to many processes

There are broadcast operations in MPI, where one process can send to all the others.

```
#include <stdio.h>
#include "mpi.h"
int main(int argc, char*argv[])
 int
                 message[10], length, root, my_rank;
 int
                 n procs, i;
 MPI Init(&argc, &argv);
 MPI_Comm_size(MPI_COMM_WORLD, &n_procs);
  MPI_Comm_rank(MPI_COMM_WORLD, &my_rank);
 length = 10;
 root = 2; /* Note: the same for all. */
              /* Need not be 2, of course. */
  if (my_rank == 2) {
   for (j = 0; j < length; j++)
           message[j] = j;
    /* Here is the broadcast. Note, no tag.*/
   MPI_Bcast(message, length, MPI_INT, root,
             MPI COMM WORLD);
  } else {
    /* The slaves have exactly the same call*/
   MPI_Bcast(message, length, MPI_INT, root,
             MPI_COMM_WORLD);
   printf("%d: message[0..2] = %d %d %d\n",
          my_rank, message[0], message[1],
          message[2]);
 MPI_Finalize();
 return 0;
                        217
```

There are other global communication routines.

Let us compute an integral by dividing the interval in #p pieces:

$$\int_a^b f(x)dx=\int_a^{a+h}f(x)dx+\int_{a+h}^{a+2h}f(x)dx+\cdots+\int_{a+(\#p-1)h}^bf(x)dx$$
 where  $h=\frac{b-a}{\#p}.$ 

Each process computes its own part, and the master has to add all the parts together. Adding parts together this way is called a reduction.

We will use the trapezoidal method (we would <u>not</u> use that in a real application).

```
#include <stdio.h>
#include <math.h>
#include "mpi.h"
/* Note */
#define MASTER 0
/* Prototypes */
double trapez(double, double, int);
double f(double);
int main(int argc, char *argv[])
{
 int
         n_procs, my_rank, msg_len;
  double a, b, interval, I, my_int, message[2];
 MPI_Init(&argc, &argv);
 MPI_Comm_size(MPI_COMM_WORLD, &n_procs);
  MPI_Comm_rank(MPI_COMM_WORLD, &my_rank);
```

218

```
if (my rank == MASTER) {
 a = 0.0; b = 4.0; /* or read some values */
  /* compute the length of the subinterval*/
 interval = (b - a) / n_procs;
 message[0] = a;
                         /* left endpoint */
 message[1] = interval;
 msg_len = 2;
 MPI_Bcast(message, msg_len, MPI_DOUBLE, MASTER,
           MPI COMM WORLD);
 /* compute my part of the integral*/
 my_int = trapez(a, a + interval, 100);
 /* my_int is the MASTER's part of the integral.
    All parts are accumulated in I, but only in
    the master process.
 msg len = 1;
 MPI_Reduce(&my_int, &I, msg_len, MPI_DOUBLE,
            MPI_SUM, MASTER, MPI_COMM_WORLD);
 printf("The integral = %e\n", I);
} else { /* I'm a slave */
 msg_len = 2;
 MPI_Bcast(message, msg_len, MPI_DOUBLE, MASTER,
           MPI_COMM_WORLD);
 /* unpack the message */
 a
       = message[0];
 interval = message[1];
 /* compute my endpoints*/
 a = a + my_rank * interval;
 b = a + interval;
                      220
```

```
/* approximate the integral */
   my_int = trapez(a, b, 100);
   msg_len = 1;
   MPI_Reduce(&my_int, &I, msg_len, MPI_DOUBLE,
              MPI_SUM, MASTER, MPI_COMM_WORLD);
 MPI_Finalize();
 return 0;
double f(double x) /* The integrand */
{
  return exp(-x * cos(x));
/* An extremely primitive quadrature method.
  Approximate integral from a to b of f(x) dx.
   We integrate over [a, b] which is different
   from the [a, b] in the main program.
double trapez(double a, double b, int n)
{
  int
           k:
 double I, h;
 h = (b - a) / n;
  I = 0.5 * (f(a) + f(b));
  for(k = 1; k < n; k++) {
   a += h;
   I += f(a);
 return h * I;
                         221
```

To get good speedup the function should require a huge amount of cputime to evaluate.

There are several operators (not only MPI\_SUM) that can be used together with MPI\_Reduce

```
MPI MAX
              return the maximum
              return the minimum
MPI MIN
              return the sum
MPI SUM
MPI_PROD
              return the product
MPI_LAND
              return the logical and
              return the bitwise and
MPI BAND
MPI_LOR
              return the logical or
MPI_BOR
              return the bitwise of
MPI_LXOR
              return the logical exclusive or
              return the bitwise exclusive or
MPI BXOR
MPI_MINLOC
              return the minimum and the location (actually, the
              value of the second element of the structure where
              the minimum of the first is found)
MPI_MAXLOC
             return the maximum and the location
```

If all the processes need the result (I) we could do a broadcast afterwards, but there is a more efficient routine, MPI\_Allreduce See the web for details (under Documentation, MPI-routines).

The MPI\_Allreduce may be performed in an efficient way. Suppose we have eight processes, 0, ..., 7. | denotes a split.

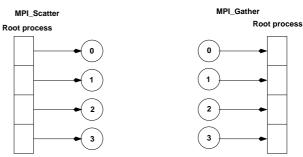

Each process accumulates its own sum (and sends it on):

```
s0 = x[0] + x[4], s2 = x[2] + x[6], ...

s0 = s0 + s2 = (x[0] + x[4] + x[2] + x[6])

s0 = s0 + s1 = x[0] + ... + x[7]
```

A common operation is to gather, MPI\_Gather (bring to one process) sets of data. MPI\_Scatter is the reverse of gather, it distributes pieces of a vector. See the manual for both of these.

There is also an MPI\_Allgather that gathers pieces to a long vector (as gather) but where each process gets a copy of the long vector. Another "All"-routine is MPI\_Allreduceas we just saw.

# Nonblocking communication - a small example

Suppose we have a pool of tasks where the amount of time to complete a task is unpredictable and varies between tasks.

We want to write an MPI-program, where each process will ask the master-process for a task, complete it, and then go back and ask for more work. Let us also assume that the tasks can be finished in any order, and that the task can be defined by a single integer and the result is an integer as well (to simplify the coding).

The master will perform other work, interfacing with the user, doing some computation etc. while waiting for the tasks to be finished.

We could divide all the tasks between the processes at the beginning, but that may lead to load inbalance.

An alternative to the solution, on the next page, is to create two threads in the master process. One thread handles the communication with the slaves and the other thread takes care of the user interface.

One has to very careful when mixing threads and MPI, since the MPI-system may not be thread safe, or not completely thread safe. The MPI-2.0 standard defines the following four levels:

- MPI\_THREAD\_SINGLE Only one thread will execute.
- MPI\_THREAD\_FUNNELED The process may be multi-threaded, but only the main thread will make MPI calls (all MPI calls are "funneled" to the main thread).
- MPI\_THREAD\_SERIALIZED The process may be multi-threaded, and multiple threads may make MPI calls, but only one at a time: MPI calls are not made concurrently from two distinct threads (all MPI calls are "serialized").
- MPI\_THREAD\_MULTIPLE Multiple threads may call MPI, with no restrictions.

See the standard for more details.

224

Details about nonblocking communication

A nonblocking send start call initiates the send operation, but does not complete it. The send start call will return before the message was copied out of the send buffer. A separate send complete call is needed to complete the communication, i.e., to verify that the data has been copied out of the send buffer.

Similarly, a nonblocking receive start call initiates the receive operation, but does not complete it. The call will return before a message is stored into the receive buffer. A separate receive complete call is needed to complete the receive operation and verify that the data has been received into the receive buffer.

This is where the master can do some work in parallel with the wait. Using a blocking receive the master could not work in parallel.

If the send mode is standard then the send-complete call may return before a matching receive occurred, if the message is buffered. On the other hand, the send-complete may not complete until a matching receive occurred, and the message was copied into the receive buffer.

Nonblocking sends can be matched with blocking receives, and vice-versa.

Here is comes a nonblocking send:

```
MPI_Request request;
```

It looks very much like a blocking send, the only differences are the name MPI\_Isend(I stands for an almost immediate return), and the extra parameter, request. The variable is a handle to a so-called opaque object. The master does the following:

```
set_of_tasks = { task_id:s }
  Send a task id to each slave and remove
  these task_id:s from set_of_tasks
  while ( not all results have been received ) {
   while ( no slave has reported a result ) // NB
     do some, but not too much, work
   if ( tasks remaining ) {
     pick a task_id from the set_of_tasks and
     remove it from the set_of_tasks
     send task_id to the slave
     (i.e. to the slave that reported the result)
    } else
     send task_id = QUIT to slave
Here is the slave code:
  dont_stop = 1 /* continue is a keyword in C*/
  while ( dont_stop ) {
   wait for task_id from master
   dont_stop = task_id != QUIT
   if ( dont_stop ) {
     work on the task
     send result to master
```

The nonblocking communication is used in the while-loop marked NB. If the master is doing too much work in the loop, in may delay the slaves.

225

Think of the communication object as being a C-structure with variables keeping track of the tag and destination etc. request is used to identify communication operations and match the operation that initiates the communication with the operation that terminates it. We are not supposed to access the information in the object, and its contents is not standardised.

A nonblocking receive may look like:

MPI\_Request request;

and here is a simplified description.  $\tt request$  is a handle to a communication object, referred to as object.

MPI\_Wait returns when the operation identified by request is complete. So it is like a blocking wait. If the object was created by a nonblocking send or receive call, then the object is deallocated and request is set to MPI\_REQUEST\_NULL

MPI\_Test returns flag = true if the operation identified by request is complete. In such a case, status contains information on the completed operation; if the object was created by a nonblocking send or receive, then it is deallocated and request is set to MPI\_REQUEST\_NULL

The call returns flag = false, otherwise. In this case, the value of status is undefined.

Finally MPI\_Testany. If the array of requests contains active handles then the execution of MPI\_Testany has the same effect as the execution of

```
MPI_Test( &requests[i], flag, status),
  for i=0, 1 ,..., count-1,
```

in some arbitrary order, until one call returns flag = true, or all fail. In the former case, index is set to the last value of i, and in the latter case, it is set to MPI\_UNDEFINED

If request (or requests) does not correspond to an ongoing operation, the routines return immediately.

Now it is time for the example. We have n\_slaves numbered from 0 up to n\_procs - 2. The master has rank n\_procs - 1. The number of tasks are n\_tasks and we assume that the number of slaves is not greater than the number of tasks. task\_ids is an array containing a non-negative integer identifying the task. A task id of QUIT = -1 tells the slave to finish.

The computed results (integers) are returned in the array results.

next\_task points to the next task in task\_ids and n\_received keeps track of how many tasks have been finished by the slaves.

228

Here comes the code. First the master-routine.

```
void master_proc(int n_procs, int n_slaves, int n_tasks
                int task_ids[], int results[])
  const int max_slaves = 10, tag = 1, msg_len = 1;
  int hit, message, n_received, slave, next_task, flag;
  double d:
  MPI_Request requests[max_slaves];
 MPI_Status status;
  next task = n received = 0;
  /* Initial distribution of tasks*/
  for (slave = 0; slave < n_slaves; slave++) {</pre>
   MPI_Send(&task_ids[next_task], msg_len, MPI_INT,
             slave, tag, MPI_COMM_WORLD);
    /* Start a nonblocking receive*/
   MPI_Irecv(&results[next_task], msg_len, MPI_INT,
             MPI_ANY_SOURCE, MPI_ANY_TAG,
             MPI_COMM_WORLD, &requests[slave]);
   next_task++;
  /* Wait for all results to come in ...*/
  while (n_received < n_tasks) {
   flag = 0;
   while (!flag) {
      /* Complete the receive */
     MPI_Testany(n_slaves, requests, &hit, &flag,
                 &status);
      d = master_work(); /* Do some work */
```

229

```
n received++;
                            /* Got one result */
slave = status.MPI_SOURCE; * from where?
/* Hand out a new task to the slave,
  unless we are done
if (next_task < n_tasks) {</pre>
 MPI_Send(&task_ids[next_task], msg_len, MPI_INT,
          slave, tag, MPI_COMM_WORLD);
 MPI_Irecv(&results[next_task], msg_len, MPI_INT,
           MPI_ANY_SOURCE, MPI_ANY_TAG,
           MPI_COMM_WORLD, &requests[hit]);
  next task++;
} else { /* No more tasks */
  message = QUIT;
  MPI_Send(&message, msg_len, MPI_INT, slave, tag,
          MPI COMM WORLD);
```

```
and then the code for the slaves
void slave_proc(int my_rank, int master)
  const int msg_len = 1, tag = 1;
  int message, result, dont_stop;
  MPI_Status status;
  dont stop = 1;
  while (dont_stop) {
   MPI_Recv(&message, msg_len, MPI_INT, master,
             MPI_ANY_TAG, MPI_COMM_WORLD, &status);
    dont_stop = message != QUIT;
    if (dont_stop) {
      /* Simulate work */
      result = 100 * message + my_rank;
      sleep(message);
      MPI_Send(&result, msg_len, MPI_INT, master,
               tag, MPI_COMM_WORLD);
 }
}
```

230

}

Suppose we are using three slaves and have ten tasks, the task\_ids-array takes indices from zero to nine.

The work is simulated by using the sleep-function and the ten tasks correspond to sleeping 1, 2, 3, 1, 2, 3, 1, 2, 3, 1 seconds. The work done by the master, in master\_work takes 0.12 s per call.

The table below shows the results from one run.

When a number is repeated two times the slave worked with this task for two seconds (similarly for a repetition of three).

	s]	Laves	3	task number	sleep time
	0	1	2	0	1
time				1	2
1	0	1	2	2	3
2	3	1	2	3	1
4	5	4	2	4	2
4	5	4	6	5	3
5	5	7	8	6	1
6	9	7	8	7	2
7			8	8	3
				9	1

So had it been optimal, the run should have taken 7 s wallclock time (the sum of the times is 19, so it must take more than 6 s wallclock time, as  $3\cdot 6 < 19$ . The optimal time must be an integer, and the next is 7). The time needed was 7.5 s and the master was essentially working all this time as well.

Using two slaves the optimal time is 10 s, and the run took 10.8 s.

# A page about distributed Gaussian elimination

In standard GE we take linear combinations of rows to zero elements in the pivot columns. We end up with a triangular matrix.

How should we distribute the matrix if we are using MPI?

The obvious way is to partition the rows exactly as in our power method (a row distribution). This leads to poor load balancing, since as soon as the first block has been triangularized processor 0 will be idle.

After two elimination steps we have the picture (x is nonzero and the block size is 2):

x	x	x	x	x	x	x	x	proc	0
0	x	x	x	x	x	x	x	proc	0
0	0	x	x	x	x	x	x	proc	1
0	0	x	x	x	x	x	x	proc	1
0	0	x	x	x	x	x	x	proc	2
0	0	x	x	x	x	x	x	proc	2
0	0	x	x	x	x	x	x	proc	3
0	0	x	x	x	x	x	x	proc	3

Another alternative is to use a cyclic row distribution. Suppose we have four processors, then processor 0 stores rows 1, 5, 9, 13, ... Processor 2 stores rows 2, 6, 10 etc. This leads to a good balance, but makes it impossible to use BLAS2 and 3 routines (since it is vector oriented).

There are a few other distributions to consider, but we skip the details since they require a more thorough knowledge about algorithms for GE.

233

# One word about Scalapack

ScaLAPACK (Scalable Linear Algebra PACKage) is a distributed and parallel version of Lapack. ScaLAPACK uses BLAS on one processor and distributed-memory forms of BLAS on several (PBLAS, Parallel BLAS and BLACS, C for Communication). BLACS uses PVM or MPI.

Scalapack uses a block cyclic distribution of (dense) matrices. Suppose we have processors numbered  $0,\,1,\,2$  and 3 and a block size of 32. This figure shows a matrix of order  $8\,\cdot\,32$ .

It turns out that this layout gives a good opportunity for parallelism, good load balancing and the possibility to use BLAS2 and BLAS3.

Doing a Cholesky factorization on the Sun using MPI:

n = 4000 block size = 32

#CPUs = 4 time = 27.5 rate = 765 Mflops

The uniprocessor Lapack routine takes 145s.

#### Some other things MPI can do

- Suppose you would like to send an int, a double array, and int array etc. in the same message. One way is to pack things into the message yourself. Another way is to use MPI\_Pack/MPI\_Unpack or (more complicated) to create a new MPI datatype (almost like a C-structure).
- It is possible to divide the processes into subgroups and make a broadcast (for example) in this group.
- You can create virtual topologies in MPI, e.g. you can map the processors to a rectangular grid, and then address the processors with row- and column-indices.
- $\bullet$  There is some support for measuring performance.
- It is possible to control how a message is passed from one process to another. Do the processes synchronise or is a buffer used, for example.
- There are more routines for collective communication.

In MPI-2.0 there are several new features, some of these are:

- Dynamic process creation.
- One-sided communication, a process can directly access memory of another process (similar to shared memory model).
- Parallel I/O, allows several processes to access a file in a co-ordinated way.

004

# Matlab and parallel computing

Two major options.

- 1. Threads & shared memory by using the parallel capabilities of the underlying numerical libraries.
- 2. Message passing by using the "Distributed Computing Toolbox" (a large toolbox, the User's Guide is 529 pages).

Threads can be switched on in two ways. From the GUI: Preferences/General/Multithreading or by using maxNumCompThreads Here is a small example:

```
for thr = 1:4
 maxNumCompThreads(thr); % set #threads
  j = 1;
  for n = [800 \ 1600 \ 3200]
   A = randn(n);
    B = randn(n);
    t = clock;
     C = A * B;
    T(thr, j) = etime(clock, t);
    j = j + 1;
  end
end
The speedup depends on the library. This is how you can find
% setenv LAPACK_VERBOSITY 1
cpu_id: x86 Family 15 Model 1 Stepping 0, AuthenticAMD
  etc.
libmwblas: loading acml.so
libmwblas: resolved caxpy_ in 0x524c10
libmwblas: resolved ccopy_ in 0x524c10
etc.
```

236

```
So ACML is used. Another, slower alternative is using MKL
(see the gui-help for BLAS_VERSION).
```

We tested solving linear systems and computing eigenvalues as well. Here are the times using one to four threads:

n	C = A * B			$x = A \setminus b$				l = eig(A)				
	1	2	3	4	1	2	3	4	1	2	3	4
800	0.3	0.2	0.1	0.1	0.2	0.1	0.1	0.1	3.3	2.5	2.4	2.3
1600	2.1	1.1	0.8	0.6	1.1	0.7	0.6	0.5	20	12	12	12
3200	17.0	8.5	6.0	4.6	7.9	4.8	4.0	3.5	120	87	81	80

So, using several threads can be an option if we have a large problem. We get a better speedup for the multiplication, than for eig, which seems reasonable.

This method can be used to speed up the computation of elementary functions as well.

Now to a simple example using the Toolbox.

The programs computes the eigenvalues of  $T + \rho E$  where T is a tridiagonal matrix,  $E = e_n e_n^T$  and  $\rho$  is a real parameter.

Here are the times (to save space):

n	t1	t2	t3
500	10.58	1.63	1.00
1000	18.84	2.40	3.89
2000	16.77	5.38	15.07
4000	39.18	16.49	58.11

t1 - t2 gives the overhead for starting the processes.

For large problems this can be useful. The toolbox can handle more complex problems, see the User's Guide for details. Here comes the program:

237

```
j = 1;
T = [];
m = 100;
params = linspace(0, 1);
for n = [500\ 1000\ 2000\ 4000]
 T = spdiags(ones(n, 3), -1:1, n, n); % create data
 E = sparse(n, n, 1);
  eigs_p = zeros(n, m);
                                         % preallocate
  t1 = clock;
   matlabpool open 4
                                         % 4 new Matlabs
    t2 = clock;
                                        % parallel loop
      parfor(k = 1:m)
       eigs_p(:, k) = eig(T + params(k) * E);
      end
    t2 = etime(clock, t2);
```

```
matlabpool close
                                        % close
 t1 = etime(clock, t1);
% The same computation one one CPU
 eigs_s = zeros(n, m);
 t3 = clock;
   for k = 1:m
     eigs_s(:, k) = eig(T + params(k) * E);
 t3 = etime(clock, t3);
 times(j, :) = [t1, t2, t3]
                                        % save times
 j = j + 1;
end
```

## OpenMP - shared memory parallelism

OpenMP is a specification for a set of compiler directives, library routines, and environment variables that can be used to specify shared memory parallelism in Fortran and C/C++ programs.

Fortran version 1.0, Oct 1997, ver. 2.0 Nov. 2000. C/C++ ver. 1.0 Oct. 1998, ver. 2.0 Mar. 2002.

Version 2.5 May 2005, combines the Fortran and C/C++ specifications into a single one and fixes inconsistencies.

Specifications (in PDF): www.openmp.org Good readability to be standards.

From www: The public discussion period for the draft OpenMP  $3.0~{\rm specifications}$  closed in January. The draft is now under final review by the Architecture Review Board (ARB), with a final vote due in a few weeks. Stay tuned. Posted on April 29, 2008

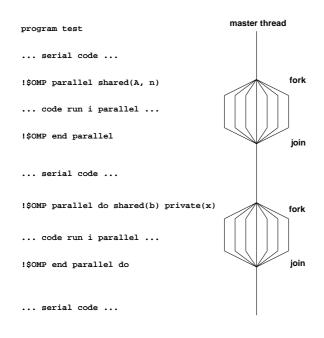

#### Books:

Parallel Programming in OpenMP, R Chandra, D Kohr, R Menon, L Dagum, D Maydan, J McDonald.

Morgan Kaufmann, 2000. 231 pages.

Parallel Programming in C with MPI and OpenMP, M J Quinn. McGraw-Hill Education, 2003. 544 pages.

Patterns for Parallel Programming, T Mattson, B Sanders, B Massingill. Addison Wesley Professional, 2004, 384 pages. Basic idea - fork-join programming model

- when reaching a parallel part the master thread (original process) creates a team of threads and it becomes the master of the team
- the team execute concurrently on different parts of the loop (parallel construct)
- upon completion of the parallel construct, the threads in the team synchronise at an implicit barrier, and only the master thread continues execution
- the number of threads in the team is controlled by environment variables and/or library calls, e.g. setenv OMP\_NUM\_THREADS 7 call omp\_set\_num\_threads(5)
- the code executed by a thread must not depend on the result produced by a different thread

So what is a thread?

A thread originates from a process and is a part of that process. The threads (belonging to the particular process) share global variables, files, code, PID etc. but they have their individual stacks and program counters.

Note that we have several processes in MPI.

Since all the threads can access the shared data (a matrix say) it is easy to write code so that threads can work on different parts of the matrix in parallel.

It is possible to use threads directly but we will use the OpenMP-directives. The directives are analysed by a compiler or preprocessor which produces the threaded code.

241

#### MPI versus OpenMP

240

Parallelising using distributed memory (MPI):

- Requires large grain parallelism to be efficient (process based).
- Large rewrites of the code often necessary difficult with "dusty decks".
   May end up with parallel and non-parallel versions.
- $\bullet$  Domain decomposition; indexing relative to the blocks.
- Requires global understanding of the code.
- Hard to debug.
- Runs on most types of computers.

Using shared memory (OpenMP)

- Can utilise parallelism on loop level (thread based). Harder on subroutine level, resembles MPI-programming.
- Minor changes to the code necessary. A detailed knowledge of the code not necessary. Only one version.
   Can parallelise using simple directives in the code.
- $\bullet$  No partitioning of the data.
- Less hard to debug.
- Not so portable; requires a shared memory computer.
- Less control over the "hidden" message passing and memory allocation.

#### A simple example

Not all compilers support the full 2.5-standard and compiler flags may differ. In order for of program of this type to be efficient n must be fairly large.

```
1 program example
     use omp_lib ! or include "omp_lib.h"
2
3
                 ! or something non-standard
     implicit none
 4
5
     integer
                                    :: i, i am
 6
     integer, parameter
                                    :: n = 10000
    double precision, dimension(n) :: a, b, c
8
     c = 1.242d0 ! can be used inside the loop
10 !$omp parallel do private(i), shared(a, b, c)
11
     do i = 1, n
12
      b(i) = 0.5d0 * i
13
      a(i) = 1.23d0 * b(i) + 3.45d0 * c(i)
14
     end do
15 !$omp end parallel do
                         ! not necessary
16
17
    print*, a(1), a(n)
                          ! only the master
18
19 !$omp parallel private(i_am) ! a parallel region
    i_am = omp_get_thread_num()! 0, ..., #threads - 1
20
21
     print*, 'i_am = ', i_am
22
23
     !$omp master
      print*, 'num threads = ', omp_get_num_threads()
24
      print*, 'max threads = ', omp_get_max_threads()
25
      print*, 'max cpus = ', omp_get_num_procs()
26
27
     !$omp end master
28
29 !$omp end parallel
30
31 end program example
```

242

10: A parallel do-loop. !\$omp or !\$OMP. See the standard for Fortran77.

Use shared when:

- a variable is not modified in the loop or
- when it is an array in which each iteration of the loop accesses a different element

All variables except the loop-iteration variable are shared by default. To turn off the default, use default (none).

Suppose we are using four threads. The first thread may work on the first 2500 iterations (n = 10000), the next thread on the next group of 2500 iterations etc.

15: Not necessary, the end do on line 14 is sufficient. When the threads join at the end do they synchronise, there is an implicit barrier.

19-29: A parallel region. The code in the region is run in parallel.

20: i\_am will be the number of the current thread. Threads are numbered from zero to the number of threads minus one.

21: All threads will print. Output from several threads may be interleaved (you may need a special compiler).

23-27: To avoid multiple prints we ask the master thread (thread zero) to print. Number of executing threads, maximum number of threads that can be created (can be changed by setting OMP\_NUM\_THREADS or by calling omp\_set\_num\_threads) and available number of processors (cpus).

% f90 -mp omp1.f90 -lmp May need special library % setenv OMP\_NUM\_THREADS 1 % a.out 3.8801893470010604, 6153.2651893470011 i\_am = 0 num threads = 1 max threads = max cpus = 8 % setenv OMP\_NUM\_THREADS 4 3.8801893470010604, 6153.2651893470011  $i_am = 0$ iam = 2num threads = 4 iam = 3max threads = 4 i am = 1 max cpus % setenv OMP\_NUM\_THREADS 9 % a.out Warning: MP\_SET\_NUMTHREADS greater than available cpus (set to 9; cpus = 8) 3.8801893470010604, 6153.2651893470011 i\_am = 2 num threads = 9 i am = 8 max threads = 9

Make no assumptions about the order of execution between threads. Output from several threads may be interleaved (you may need a special compiler).

On Itanium: ifort -openmp ... New this year: gcc -fopenmp ..., gfortran -fopenmp ...

245

244

#### The same program in C

```
#include <stdio.h>
#include <omp.h>
#define _N 10000
int main()
{
 int
                 i, i_am;
  const int
                n = N;
  double
                 a[_N], b[_N], c[_N];
 for (i = 0; i < n; i++)
    c[i] = 1.242;
/* pragma omp instead of !$omp*/
#pragma omp parallel for private(i) shared(a, b, c)
  for (i = 0; i < n; i++) {
   b[i] = 0.5 * (i + 1);
    a[i] = 1.23 * b[i] + 3.45 * c[i];
 printf("%f, %f\n", a[0], a[n - 1]);
#pragma omp parallel private(i_am)
    i_am = omp_get_thread_num();
    printf("i_am = %d\n", i_am);
#pragma omp master
    {
    printf("num threads = %d\n",omp_get_num_threads())
    printf("max threads = %d\n",omp_get_max_threads())
    printf("max cpus
                       = %d\n",omp_get_num_procs());
     /* Pairs of { } instead of end*/
 return 0;
}
```

#### **Problems**

```
program ex2
!$omp parallel do private(i), shared(a)
do i = 1, 1000
a = i
```

end do

Do not do like this:

print\*, a

end program ex2

Will give you different values 1000., 875. etc.

```
program ex3
 integer
                        :: i
  integer, dimension(12) :: a, b
  a = 1 ! a vector of ones
 b = 2
!$omp parallel do private(i) shared(a, b)
 do i = 1, 11
   a(i + 1) = a(i) + b(i)
  end do
  print*, a
end program ex3
1, 3, 5, 7, 9, 11, 13, 15, 17, 19, 21, 23 one thread
1, 3, 5, 7, 9, 11, 13, 3, 5, 7, 9, 11 four
1, 3, 5, 7, 9, 11, 13, 15, 17, 19, 3, 5 four
1, 3, 5, 7, 9, 11, 13, 3, 5, 7, 3, 5 four
```

#### Why?

thread	computation	
0	a(2) = a(1) + b(1)	
0	a(3) = a(2) + b(2)	
0	a(4) = a(3) + b(3)	<
		Problem
1	a(5) = a(4) + b(4)	<
1	a(6) = a(5) + b(5)	
1	a(7) = a(6) + b(6)	<
		Problem
2	a(8) = a(7) + b(7)	<
2	a(9) = a(8) + b(8)	
2	a(10) = a(9) + b(9)	<
		Problem
3	a(11) = a(10) + b(10)	<
3	a(12) = a(11) + b(11)	

We have a data dependency between iterations, causing a so-called <u>race condition</u>.

Can "fix" the problem:

! You need ordered in both places

```
!$omp parallel do private(i) shared(a, b) ordered
do i = 1, 11
   !$omp ordered
      a(i + 1) = a(i) + b(i)
   !$omp end ordered
end do
```

but in this case the threads do not run in parallel.

248

Suppose we parallelize m iterations over P processors. No default scheduling is defined in the OpenMP-standard, but schedule(static, m / P) is a common choice (assuming that P divides m).

Here comes an example where this strategy works badly. So do not always use the standard choice.

We have nested loops, where the number of iterations in the inner loop depends on the loop index in the outer loop.

Suppose m is large and let  $T_{ser}$  be the total run time on one thread. If there is no overhead, the time,  $T_t$ , for thread number t is approximately:

$$T_t pprox rac{2T_{ser}}{P} \, \left(1 - rac{t+1/2}{P}
ight), \;\; t=0,\ldots,P-1$$

So thread zero has much more work to do compared to the last thread:

$$\frac{T_0}{T_{P-1}} \approx 2P - 1$$

a very poor balance. The speedup is bounded by  $T_0$ :

$${
m speedup} = rac{T_{ser}}{T_0} pprox rac{P}{2}$$

and not the optimal P.

#### Load balancing

!\$omp parallel do private(k) shared(x, n) &

Default chunk, roughly = n / number\_of\_threads

Low overhead, good if the same amount of work in each iteration. chunk can be used to access array elements in groups (may be me more efficient, e.g. using cache memories in better way).

Threads compete for chunk-sized assignments. Useful if the amount of work varies between iterations.

There is also schedule(guided, chunk)assigning pieces of work ( $\geq$  chunk) proportional to the number of remaining iterations divided by the number of threads. It requires fewer synchronisations than dynamic.

249

### The reduction clause

Reducing a vector expression to a scalar is called a reduction.

In general:
reduction(operator or intrinsic: variable list)

Valid operators are: +, -, \*, .and., .or., .eqv., .neqv. and intrinsics: max, min, iand, ior, ieor(the iand is bitwise and, etc.)

The operator/intrinsic must be used in one of the following ways:

- $\bullet x = x$  operator expression
- x = expression operator x(except for subtraction)
- x = intrinsic(x, expression)
- x = intrinsic(expression, x)

where  ${\tt expression}\,{\rm does}$  not involve  ${\tt x}.$ 

This is what happens in our example above:

- $\bullet$  each thread gets its local sum-variable,  $s_{\#thread}$  say
- $s_{\#thread} = 0$  before the loop (the thread private variables are initialised in different ways depending on the operation, zero for + and -, one for \*). See the standard for the other cases.
- ullet each thread computes its sum in  $s_{\#thread}$
- $\bullet$  after the loop all the  $s_{\#thread}$  are added to  ${\tt s}$  in a safe way

We can implement our summation example without using reduction variables. The problem is to update the shared sum in a safe way. This can be done using critical sections.

```
double precision :: private_s, shared_s
  shared_s = 0.0d0
! This is a more general parallel construct.
! Not only the do-loop is done in parallel.
!$omp parallel private(private_s) &
!$omp
              shared(x, y, shared_s, n)
 private_s = 0.0d0
                         ! Here comes the loop:
!$omp do private(i)
  do i = 1, n
   private_s = private_s + x(i) * y(i)
  end do
!$omp end do
! Here we specify a critical section.
! Only one thread at a time may pass through.
!$omp critical
 shared_s = shared_s + private_s
!$omp end critical
!$omp end parallel
  print*, shared_s
```

252

nic Here

Misuse of critical, atomic

Do not use critical sections and similar constructions too much.

This test compares three ways to compute a sum. We try reduction, critical and atomic.  $n=10^7$ .

```
do n thr = 1.4
    call omp_set_num_threads(n_thr)
    s = 0.0d0
    t = omp_get_wtime()
    !$omp parallel do reduction(+: s) private(i)
    do i = 1, n
      s = s + sqrt(dble(i))
    end do
   print '(i4, f10.3)', n_thr, omp_get_wtime() - t
  end do
  print*, s
Change the inner loop to
    !$omp parallel do shared(s) private(i)
    do i = 1, n
      !$omp critical
        s = s + sqrt(dble(i))
      !$omp end critical
    end do
and then to
    !$omp parallel do shared(s) private(i)
    do i = 1, n
     !$omp atomic
      s = s + sqrt(dble(i))
    end do
atomic updates a single variable atomically.
```

Here are the times (on Lucidor):

```
n_thr
        time, reduction
        0.066
 1
  2
        0.034
        0.023
  3
  4
        0.020
n_thr
         time, critical
         1.59
 1
 2
         4.99
  3
         6.58
  4
         6.60
n_thr
         time, atomic
         1.59
 2
         4.99
 3
         6.58
         6.73
```

We get a slowdown instead of a speedup, when using critical or atomic.

253

#### Nested loops, matrix-vector multiply

```
a = 0.0
do j = 1, n
   do i = 1, m
    a(i) = a(i) + C(i, j) * b(j)
   end do
end do
```

Can be parallelised with respect to i but not with respect to j (since different threads will write to the same a(i)).

May be inefficient since parallel execution is initiated  $\tt n$  times (procedure calls). OK if  $\tt n$  small and  $\tt m$  large.

Switch loops.

```
a = 0.0
do i = 1, m
  do j = 1, n
    a(i) = a(i) + C(i, j) * b(j)
  end do
end do
```

The do i can be parallelised. Bad cache locality for C.

Test on KALLSUP2 (Power3), using -03 (implies blocking). Times in seconds for one to four threads. dgemv takes 0.18s.

m	n	first loop				se	second loop			
		1	2	3	4	1	2	3	4	
4000	4000	0.3	0.2	0.2	0.2	5.9	3.1	2.1	1.6	
40000	400	0.3	0.2	0.1	0.1	3.5	1.8	1.2	0.9	
400	40000	0.3	1.0	1.0	1.2	11.4	6.7	4.9	4.1	

 $\bullet$  Cache locality is important.

! a, b and c are arrays

... code

- $\bullet$  If second loop necessary, OpenMP gives speedup.
- $\bullet$  Large n gives slowdown in first loop.

256

Some, but not all, compilers support parallelization of Fortran90 array operations, e.g.

Here comes a first example of where we call a subroutine from a parallel region.

# Some other OpenMP directives

```
!$omp parallel shared(a, n)
                            ! a parallel region
       ... code run in parallel
!$omp single ! only ONE thread will execute the code
       ... code
!$omp end single
!$omp barrier ! wait for all the other threads
     ... code
!Somp do private(k)
       do ..
       end do
!$omp end do nowait ! don't wait (to wait is default)
     do ... ! NOTE: all iterations run by all threads
     end do
!$omp sections
         ... code executed by one thread
      section
         ... code executed by another thread
!$omp
      section
         ... code executed by yet another thread
!$omp end sections ! implicit barrier
!$ Fortran statements ... Included if we use OpenMP,
!$ but not otherwise (conditional compilation)
!$omp end parallel ! end of the parallel section
```

257

```
program example
 use omp lib
  implicit none
 integer, dimension(0:3) :: a = 99
                         :: i am
!$omp parallel private(i_am) shared(a)
       i_am = omp_get_thread_num()
       call work(a, i_am)
!$omp
       single
         print*, 'a = ', a
gmoż!
       end single
!$omp end parallel
end program example
subroutine work(a, i am)
! Dummy arguments inherit the data-sharing
! attributes of the associated actual arguments.
  integer, dimension(0:3) :: a ! becomes shared
  integer
                         :: i am ! becomes private
 print*, 'work', i_am
 a(i_am) = i_am
end subroutine work
% a.out
work 1
work 3
a = 99, 1, 99, 3
work 2
work 0
```

```
Print after !$omp end parallel(or add a barrier):
!$omp barrier
!$omp single
    print*, 'a = ', a
!$omp end single

% a.out
work 0
work 1
work 3
work 2
a = 0, 1, 2, 3
```

There are more things in the standard (directives, locking routines).

OpenMP makes no guarantee that input or output to the same file is synchronous when executed in parallel. You may need to link with a special thread safe I/O-library.

260

```
!$omp parallel shared(s) private(p) ---
!$omp do
       do j = 1, m
                                   | lexical extent
                                   of the
       end do
                                   parallel region
                                   | (dynamic as
     call sub(s, p)
                                   | well)
!$omp end parallel
! -----
subroutine sub(s, p)
 integer :: s
                       ! shared
                       ! private
 integer
         :: p
 integer :: local_var ! private
!$omp do ...
      do k = 1, n
                         | dynamic extent of the
        . . .
       end do
                          parallel region
!$omp end do
end subroutine sub
```

The !\$omp do in sub is an orphaned directive (it appears in the dynamic extent of the parallel region but not in the lexical extent). This do binds to the dynamically enclosing parallel directive and so the iterations in the do will be done in parallel (they will be divided between threads). Lexical/dynamic terminology from ver. 2.0 but easier to understand.

# More on OpenMP and subprograms

A few examples:

- Calling a subroutine, containing OpenMP-directives, from a serial part of the program. Essentially what we have done so far.
- Suppose now that we have the following situation:

```
!$omp parallel ...
    ... code
        call a parallel subroutine
    ... code
!$omp end parallel ...
```

i.e. we are calling a subroutine, containing OpenMP-directives, from a parallel part of the program.

To understand what happens we have to read (part of) the following sections (ver. 2.0, integrated in the new version) in the OpenMP standard:

- "Data Environment Rules", details about data scope, what becomes private, shared.
- "Directive Binding": Rules with respect to the dynamic binding of directives. What happens if we put a loop in a subroutine called from a parallel region?
- "Directive Nesting". What happens if we put a parallel region inside a parallel region, for example?

We need to have heard the term "Orphaned Directives" as well.

26

Suppose now that **sub** contains the following three loops and that we have three threads:

```
character (len = *), parameter :: f = '(a, 3i5)'
 i_am = omp_get_thread_num()
!$omp do private(k)
       do k = 1, 6
                         ! LOOP 1
        print f, '1:', i_am, omp_get_thread_num(), k
       end do
!$omp end do
       do k = 1, 6
                         ! LOOP 2
        print f, '2:', i_am, omp_get_thread_num(), k
       end do
!$omp parallel do private(k)
       do k = 1, 6 ! LOOP 3
         print f, '3:', i_am, omp_get_thread_num(), k
       end do
!$omp end parallel do
```

In LOOP 1 thread 0 will do the first two iterations, thread 1 performs the following two and thread 2 takes the last two. In LOOP 2 all threads will do the full six iterations. In the third case we have:

A PARALLEL directive dynamically inside another PARALLEL directive logically establishes a new team, which is composed of only the current thread, unless nested parallelism is established.

We say that the loops is serialized. All threads perform six iterations each.

262

If we want the iterations to be shared between new threads we can set an environment variable, setenv OMP\_NESTED TRUE, or call omp set nested(.true.).

If we enable nested parallelism we get three teams consisting of three threads each, in this example.

This is what the (edited) printout from the different loops <u>may</u> look like. omp() is the value reurned by omp\_get\_thread\_num() The output from the loops may be interlaced though.

	$\mathtt{i}_\mathtt{am}$	omp()	k		$\mathtt{i}_\mathtt{am}$	omp(	) k

# Case study I: solving a large and stiff IVP

 $y'(t)=f(t,y(t)),\ y(0)=y_0,\ y,\ y_0\in\Re^n,\ f:\Re\times\Re^n\to\Re^n$  where f(t,y) is expensive to evaluate.

 ${\bf LSODE\ (Livermore\ Solver\ for\ ODE,\ Alan\ Hindmarsh)\ from\ netlib.}$   ${\bf BDF\ routines;\ Backward\ Differentiation\ Formulas.}$ 

Implicit method:  $t_k$  present time,  $y^{(k)}$  approximation of  $y(t_k)$ .

Backward Euler (simplest BDF-method). Find  $y^{(k+1)}$  such that:

$$y^{(k+1)} = y^{(k)} + hf(t_{k+1}, y^{(k+1)})$$

LSODE is adaptive (can change both h and the order).

Use Newton's method to solve for  $z \equiv y^{(k+1)}$ :

$$z - y^{(k)} - hf(t_{k+1}, z) = 0$$

One step of Newton's method reads:

$$z^{(i+1)} = z^{(i)} - \left[I - h\frac{\partial f}{\partial y}(t_{k+1}, z^{(i)})\right]^{-1}(z^{(i)} - y^{(k)} - hf(t_{k+1}, z^{(i)}))$$

The Jacobian  $\frac{\partial f}{\partial y}$  is approximated by finite differences one column at a time. Each Jacobian requires n evaluations of f.

$$rac{\partial f}{\partial y} \, e_j pprox \left[ f(t_{k+1}, z^{(i)} + e_j \delta_j) - f(t_{k+1}, z^{(i)}) 
ight] / \delta_j$$

 $e_j$  is column j in the identity matrix I.

Parallelise the computation of the Jacobian, by computing columns in parallel. Embarrassingly parallel.

264

Major costs in LSODE:

- 1. Computing the Jacobian, J, (provided f takes time).
- 2. LU-factorization of the Jacobian (once for each time step).
- 3. Solving the linear systems, given L and U.

What speedup can we expect?

Disregarding communication, the wall clock time for p threads, looks something like (if we compute J in parallel):

$$wct(p) = time(\text{LU}) + time(\text{solve}) + \frac{time(\text{computing J})}{p}$$

If the parallel part, "computing J", dominates we expect good speedup at least for small p. Speedup may be close to linear, wct(p) = wct(1)/p.

For large p the serial (non-parallel) part will start to dominate.

How should we speed up the serial part?

- 1. Switch from Linpack, used in LSODE, to Lapack.
- 2. Try to use a parallel library like  ${\tt complib.sgimath\_mp}({\tt SGI}).$

This is an old test of solving using **dposv** to solve a full, positive definite, and symmetric Ax = b-problem, n = 2500:

> f90 -O3 main.f -lcomplib.sgimath\_mp -lmp

р	time command	p	time command
1	22.58	5	8.61
2	13.75	6	8.06
3	10.80	7	7.58
4	9.42	8	7.35

After having searched LSODE (Fortran 66):

c if miter = 2, make n calls to f to approximate j.

265

100 call dgesl (wm(3), n, n, iwm(21), x, 0)

```
We see that \mathbf{r}=\delta_j fac =-h/\delta_j tn =t_{k+1} ftem =f(t_{k+1},z^{(i)}+e_j\delta_j) wm(2...) is the approximation to the Jacobian.
```

From reading the code: neq is an array but neq(1) = n

The parallel version

- j, i, yj, r, fac, ftemare private ftem is the output (y') from the subroutine
- j1 = 2 offset in the Jacobian; use wm(i+2+(j-1)\*n) no index conflicts
- srur, r0, ewt, h10, wm, savf, n, trare shared
- y is a problem since it is modified. shared does not work.
   private(y) will <u>not</u> work either; we get an <u>uninitialised</u> copy.

In the revision of the OpenMP-standard there is firstprivate which makes a private and initialised copy.

```
c$omp parallel do private(j, yj, r, fac, ftem)
c$omp+ shared(f, srur, r0, ewt, h10, wm, savf,n,neq,tn)
c$omp+ firstprivate(y)
    do j = 1,n
        yj = y(j)
        r = dmax1(srur*dabs(yj),r0/ewt(j))
        y(j) = y(j) + r
        fac = -h10/r
        call f (neq, tn, y, ftem)
        do i = 1,n
            wm(i+2+(j-1)*n) = (ftem(i) - savf(i)*fac
        end do
        y(j) = yj
        end do
```

Did not converge! After reading of the code:

```
dimension neq(1), y(1), yh(nyh,1), ewt(1), ftem(1)
change to
dimension neq(1), y(n), yh(nyh,1), ewt(1), ftem(n)
```

268

#### Case study II: sparse matrix multiplication

Task: given a matrix  $\boldsymbol{A}$  which is large, sparse and symmetric we want to:

- compute a few of its smallest eigenvalues OR
- solve the linear system Ax = b

n is the dimension of A and nz is the number of nonzeros.

Some background, which you may read after the lecture:

We will study iterative algorithms based on forming the Krylov subspace:  $\{v, Av, A^2v, \ldots, A^{j-1}v\}$ . v is a random-vector. So, Paige-style Lanczos for the eigenvalue problem and the conjugate-gradient method for the linear system, for example. When solving Ax = b we probably have a preconditioner as well, but let us skip that part.

The vectors in the Krylov subspace tend to become almost linearly dependent so we compute an orthonormal basis of the subspace using Gram-Schmidt. Store the basis-vectors as columns in the  $n \times j$ -matrix  $V_j$ .

Project the problem onto the subspace, forming  $T_j = V_j^T A V_j$  (tridiagonal) and solve the appropriate smaller problem, then transform back.

 $T_j$  and the basis-vectors can be formed as we iterate on j. In exact arithmetic it is sufficient to store the three latest v-vectors in each iteration.

26

p is the maximum number of iterations.

A Lanczos-algorithm may look something like:

	# operations
$v = \mathtt{randn}(\mathtt{n, 1})$	$\mathcal{O}(n)$
$v = v/  v  _2$	$\mathcal{O}(n)$
for $j = 1$ to $p$ do	
t=Av	$\mathcal{O}(nz)$
if $j > 1$ then $t = t - \beta_{j-1}w$ endif	$\mathcal{O}(n)$
$lpha_j = t^T v$	$\mathcal{O}(n)$
$t=t-lpha_i v$	$\mathcal{O}(n)$
$eta_i =   t  _2$	$\mathcal{O}(n)$
w = v	$\mathcal{O}(n)$
$v=t/eta_{j}$	$\mathcal{O}(n)$
Solve the projected problem and	$\mathcal{O}(j)$
and check for convergence	
end for	

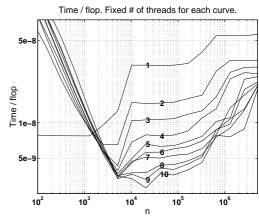

The diagonal of  $T_j$  is  $\alpha_1, \ldots, \alpha_j$  and the sub- and super-diagonals contain  $\beta_1, \ldots, \beta_{j-1}$ .

How can we parallelise this algorithm?

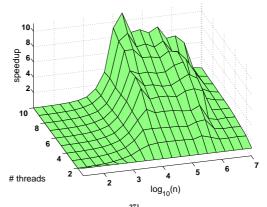

- ullet The j-iterations and the statements in each iteration must be done in order. Not possible to parallelise.
- It is easy to parallelise each of the simple vector operations (the ones that cost  $\mathcal{O}(n)$ ). May not give any speedup though.
- ullet The expensive operation in an iteration is usually Av.
- Solving the projected problem is rather fast and not so easy to parallelise (let us forget it).

We will not look at graph-based pre-ordering algorithms. A block diagonal matrix would be convenient, for example.

Vectors must not be too short if we are going to succeed. The figures show how boye (SGI) computes daxpy for different n and number of threads.

Speedup as a function of n and # threads

# The tricky part, parallelising t = Av

A is large, sparse and symmetric so we need a special data structure which takes the sparsity and the symmetry into account.

First try: store all triples  $(r,c,a_{r,c})$  where  $a_{r,c}\neq 0$  and  $r\leq c$ . I.e. we are storing the nonzeros in the upper triangle of the matrix.

The triples can be stored in three arrays, rows, cols and A or as an array of triples. Let us use the three arrays and let us change the meaning of nz to mean the number of <u>stored</u> nonzeros. The first coding attempt may look like:

```
do k = 1, nz
  if ( rows(k) == cols(k) ) then
    ... ! diagonal element
  else
    ... ! off-diagonal element
  end if
end do
```

If-statements in loops mat degrade performance, so we must think some more.

If A has a dense diagonal we can store it in a separate array, diag\_A say. We use the triples for all  $a_{r,c} \neq 0$  and r < c (i.e. elements in the strictly upper triangle).

If the diagonal is sparse we can use pairs  $(r, a_{r,r})$  where  $a_{r,r} \neq 0$ . Another way is to use the triples format but store the diagonal first, or to store  $a_{k,k}/2$  instead of  $a_{k,k}$ .

272

Our second try may look like this, where now nz is the number stored nonzeros in the strictly upper triangle of A.

```
! compute t = diag(A) * t
...

do k = 1, nz ! take care of the off-diagonals
    r = rows(k)
    c = cols(k)
    t(r) = t(r) + A(k) * v(c) ! upper triangle
    t(c) = t(c) + A(k) * v(r) ! lower triangle
end do
```

$$\begin{bmatrix} \vdots \\ t_r \\ \vdots \\ t_c \\ \vdots \end{bmatrix} = \begin{bmatrix} \ddots & \vdots & \vdots \\ \dots & a_{r,r} & \dots & a_{r,c} & \dots \\ \vdots & \ddots & \vdots \\ \dots & a_{c,r} & \dots & a_{c,c} & \dots \\ \vdots & \vdots & \vdots & \ddots \end{bmatrix} \begin{bmatrix} \vdots \\ v_r \\ \vdots \\ v_c \\ \vdots \end{bmatrix}$$

Let us now concentrate on the loops for the off-diagonals and make it parallel using OpenMP.

Note that we access the elements in A once.

This will probably give us the wrong answer (if we use more than one thread) since two threads can try to update the same t-element.

Example: The first row in A it will affect  $t_1$ ,  $t_3$  and  $t_5$ , and the second row in A will affect  $t_2$ ,  $t_4$  and  $t_5$ . So there is a potential conflict when updating  $t_5$  if the two rows are handled by different threads.

$$\begin{bmatrix} t_1 \\ t_2 \\ t_3 \\ t_4 \\ t_5 \end{bmatrix} = \begin{bmatrix} 0 & 0 & a_{1,3} & 0 & a_{1,5} \\ 0 & 0 & 0 & a_{2,4} & a_{2,5} \\ a_{1,3} & 0 & 0 & 0 & 0 \\ 0 & a_{2,4} & 0 & 0 & 0 \\ a_{1,5} & a_{2,5} & 0 & 0 & 0 \end{bmatrix} \begin{bmatrix} v_1 \\ v_2 \\ v_3 \\ v_4 \\ v_5 \end{bmatrix}$$

If the first row is full it will affect all the other rows. A block diagonal matrix would be nice.

As in the previous example it is not possible to use critical sections. Vector reduction is an option and we can do our own exactly as in case study II. Here is a slightly different version using a public matrix, instead.

 ${\tt X}$  has n rows and as many columns as there are threads,  ${\tt num\_thr}$  below. Each thread stores its sum in  ${\tt X(:, thr)}$ , where  ${\tt thr}$  is the index of a particular thread.

273

Here is the code:

```
!$omp parallel shared(X, ...)
     i_am = omp_get_thread_num() + 1
     do i = 1, n
                        ! done by all threads
       X(i, i_am) = 0.0 ! one column each
     end do
!$omp do
       do i = 1, nz
         r = rows(i)
         c = cols(i)
         X(r, i_am) = X(r, i_am) + A(i) * v(c)
         X(c, i_am) = X(c, i_am) + A(i) * v(r)
       end do
!$omp end do
!$omp do
      do i = 1, n
         do thr = 1, num_thr
          t(i) = t(i) + X(i, thr)
         end do
       end do
!Somp end parallel
```

The addition loop is now parallel, but we have bad cache locality when accessing  $\mathbf{x}$  (this can be fixed). None of the parallel loops should end with nowait.

One can get a reasonable speedup (depends on problem and system).  $\,$ 

07.

#### Compressed storage

The triples-format is not the most compact possible. A common format is the following compressed form. We store the diagonal separately as before and the off-diagonals are stored in order, one row after the other. We store cols as before, but rows now points into cols and A where each new row begins. Here is an example (only the strictly upper triangle is shown):

```
is stored as A = [ a_{1,2} \ a_{1,3} \ a_{1,5} \ | \ a_{2,3} \ a_{2,4} \ | \ 0 \ | \ a_{4,5} \ ], cols = [ \ 2 \ 3 \ 5 \ | \ 3 \ 4 \ | \ \bullet \ | \ 5 \ ], (\bullet fairly arbitrary, n say) rows = [ \ 1 \ 4 \ 6 \ 7 \ 8 \ ]. (8 is one step after the last)
```

Note that **rows** now only contains n elements. The multiplication can be coded like this (no OpenMP yet):

We can parallelise this loop (with respect to do r) in the same way as we handled the previous one (using the extra array X).

There is one additional problem though.

Suppose that the number of nonzeros per row is fairly constant and that the nonzeros in a row is evenly distributed over the columns.

If we use default static scheduling the iterations are divided among the threads in contiguous pieces, and one piece is assigned to each thread. This will lead to a load imbalance, since the upper triangle becomes narrower for increasing  $\mathbf{r}$ .

To make this effect very clear I am using a full matrix (stored using a sparse format).

A hundred matrix-vector multiplies with a full matrix of order 2000 takes (wall-clock-times):

$\# threads \rightarrow$	1	2	3	4
triple storage	19.7	10.1	7.1	6.9
compressed, static	20.1	16.6	12.6	10.1
compressed, static, 10	20.1	11.2	8.8	7.5

The time when using no OpenMP is essentially equal to the time for one thread.

276

# New in OpenMP v3.0

What we have seen so far is primarily data parallelism (SIMD), all threads perform the same operations but on different data. If different threads should perform different operations, so-called function parallelism, or task parallelism (MIMD), we can use the sections-construct, or do like this:

```
!$omp parallel private(i_am ...
    i_am = omp_get_thread_num()
    if ( i_am == 0 ) then
      ! do work 0, e.g call sub0(...)
      ...
    else if ( i_am == 1 ) then
      ! do work 1
      ...
    else if ( i_am == 2 ) then
      ...
    end if
!$omp end parallel
```

In v3.0 there is better support for "tasks", and one could write things like:

```
!$omp parallel private(...
!$omp task
    call sub0(...)
!$omp end task

do k = 1, n
    !$omp task
    call work(k)
    !$omp end task
end do
!$omp end parallel
```

277
